Master [120] in Computer Science

Abstract

It is difficult to study the detailed behaviour of large distributed systems while they are running. Many important questions are hard to answer. What happens when there is an overload? How can we feel something is wrong with the system early enough?

The purpose of the thesis is to create the ΔQ oscilloscope, a real time graphical dashboard that can be used to study the behaviour of running Erlang systems and explore tradeoffs in system design. It is based on the principles of ΔQSD .

Furthermore, we have developed an Erlang interface, the ΔQ adapter (`dqsd_otel`). It allows sending real time insights about the running system to the oscilloscope. The adapter works on top of the OpenTelemetry framework macros. This allows for users who have already instrumented their applications with OpenTelemetry to easily integrate the interface.

The oscilloscope performs statistical computations on the time series data it receives from the adapter and displays the results in real time, thanks to the ΔQSD paradigm. We provide a set of triggers to capture rare events, like an oscilloscope would, and give a snapshot of the system under observation, as if it was frozen in time. An implementation of a textual syntax allows the creation of outcome diagrams which give an “observational view” of the system. Furthermore, the implementation of efficient algorithms for complex operations, such as convolution, allows for the computations to be done rapidly on precise representations of components.

We introduce the work by giving a summary of ΔQSD concepts. We also provide a summary of the observability tools available for Erlang, namely, OpenTelemetry. We then present the overall design of the project, describing how to build a bridge from OpenTelemetry to the oscilloscope. Subsequently, we explain the user level concepts which are essential to understand how the oscilloscope works and understand what is displayed on the screen, delving later on into the mathematical foundations of the concepts. Lastly, we provide synthetic applications which prove the soundness of ΔQSD and show how the oscilloscope is able to detect problems in a running system, diagnose it and explore design tradeoffs.

Acknowledgments

This thesis is the culmination of my studies, I would like to thank the people who made this possible, those who supported me through the years and those who helped me with the thesis.

My family, especially **my mom, my dad, my brother** and **my sister**, for their help. They were a crucial shoulder I could lay on while writing this thesis and most importantly throughout these five years.

My **friends**, to those who have come from Italy and have taken time out of their lives to listen the thesis presentation, and to those who through the years have been there for me.

A-M., for the moments we shared these four years together in uni.

My dad and **Maurizio**, who nurtured the passion for coding in me.

Peer Stritzinger, Stritzinger GmbH and the **EEF Observability Working Group** (Bryan Naegele and Tristan Slougher) for their help in the EEF Slack, which helped me understand OpenTelemetry and gave me the `send_after` intuition.

Neil Davies for taking the time to proofread my thesis.

The **PNSol Ltd.** team for their extensive groundwork on ΔQSD and its dissemination, which made this thesis possible.

Lastly, **Peter Van Roy**, for his year-long relentless interest, support and weekly and constant supervision which made sure the project would come to fruition.

AI disclaimer

AI was employed to help with the graphical dashboard in C++ and the triggers, in positioning the elements, refactoring the code so the widgets would properly interact together, helping understand the FFT algorithm and refactoring the server when communication errors occurred. For the dashboard, 25% of ELOC are **refactored** by AI, they are the constructors of the widgets which nicely place the widgets on screen. The ANTLR CMake was provided by ChatGPT. In total, of around 6000 ELOC, around 10 to 15% has been done or refactored by AI, this is mostly composed of the server and dashboard/trigger code. Comments were generated by ChatGPT and reviewed so they would reflect actual code.

In Erlang, it was used to provide documentation and help with TCP communication exceptions. To give an estimate, around 20% of 350 ELOC are done or refactored by AI and they mostly relate to TCP communication and errors handling. Comments were generated and restructured to present the tools nicely.

The **written master thesis** was written **entirely** without the aid of AI.

Chapter 1

Introduction

1.1 Problem

Diagnosing and measurement of distributed systems is not a trivial task. The very nature of them makes capturing the behaviour of the different parts that compose it, that may be in different physical locations, a challenging endeavour. [1]

In 2019, the merge of OpenCensus and OpenTracing led to the creation of OpenTelemetry [2]. It aims to provide a standard set of API to monitor running systems and avoid vendor lock-in [3]. As a result, multiple vendors' monitoring tools support OpenTelemetry metrics analysis [4]. They allow engineers to follow requests in system, studying their time of execution, the paths they take, the various events and much more [5]. Nevertheless, open source non-commercial monitoring tools of large distributed system are few, and current solutions who may provide detailed insights about a system are commercial ones. [6]

Furthermore, while the tools may also provide insights about running systems and the execution times of various endpoints [7], they fail to capture essential requirements about timeliness. How can performance issues be recognised instantly? These issues may not be even apparent in these monitoring tools, as they can appear at the microseconds level. They may not be easily spotted by normal analysis of average delays. This is where the Δ QSD paradigm comes in.

1.2 Approach

In the context of this thesis, the **Δ QSD paradigm** has been used to develop a tool to study the real-time behaviour of running systems.

As described by a tutorial given on Δ QSD [8]:

“ Δ QSD is an industrial-strength approach for large-scale system design that can predict performance and feasibility early on in the design process.”

The paradigm has been developed over 30 years by the people around **Predictable Network Solutions Ltd** [9][10]. It has had various successful uses in the context of

distributed and large-scale projects. Moreover, it is the basis of Broadband forum’s TR452 standard series, used in instrumenting data networks [11].

Thanks to outcome diagrams and statistical representations of component’s behaviour, performance and feasibility can be predicted with the paradigm at high load, even if the system is not fully defined. [8] [10]

While the paradigm has been successfully applied in a **posteriori** analysis, there is no way yet to analyse a distributed system which is running in real time with Δ QSD. This is where the **Δ Q oscilloscope** comes in.

1.3 Objective

This project will develop a practical tool, the **Δ Q oscilloscope**, for the Erlang developer community.

The Erlang language and Erlang/OTP platform are widely used to develop distributed applications that must perform reliably under high load [12]. The tool will provide useful information for these applications for understanding their behaviour, for diagnosing performance issues, and for optimising performance over their lifetime. [13]

The Δ Q Oscilloscope will perform statistical computations to show real time graphs about the performance of system components. With the oscilloscope prototype we present in this thesis, we are aiming to show that the Δ QSD paradigm is not only a theoretical paradigm, but it can be employed in a real-time tool to diagnose distributed systems. Its application can then be further extended to large systems once the oscilloscope is refined.

The paradigm ideal target is “large distributed applications handling many independent tasks where performance and reliability are important” [8]. This also applies to the oscilloscope.

1.4 Previous work

The Δ QSD paradigm has been formalised across different papers [10] [14] and was brought to the attention of engineers via tutorials [8], and to students at Université Catholique de Louvain. [15]

A Jupyter notebook workbench has been made available on GitHub [16]. It is meant as an interactive tool to show how the Δ QSD paradigm can be applied to real life examples. It shows real time Δ Q graphs for typical outcome diagrams, but is not adequate to be scaled to real time systems.

Observability tools such as Erlang tracing [17] and OpenTelemetry [18] lack the notions of failure as defined in Δ QSD, which allows detecting performance problems early on. We base our program on OpenTelemetry to incorporate already existing notions of causality and observability to augment their capabilities and make them suitable to work with the Δ QSD paradigm.

1.5 Contributions

We make the following principal contributions in the master thesis:

- The ΔQ oscilloscope, from design to implementation, to plot real-time ΔQ graphs. The oscilloscope contributions include:
 - A graphical interface in Qt.
 - The underlying implementation of ΔQSD concepts, including a textual syntax to create outcome diagrams derived from the original algebraic syntax.
 - Efficient convolution algorithms.
 - A system of triggers to catch rare events, when system behaviour fails to meet quality requirements.
- The ΔQ adapter to communicate from the Erlang application to the oscilloscope.
- The evaluation of the effectiveness of the oscilloscope on synthetic applications.
- The evaluation of the efficiency of the basic operations regarding the oscilloscope, convolution, graphing and the adapter overhead.

These contributions can show that the ΔQSD paradigm can be translated from a posteriori analysis to real-time observation of running system. Furthermore, it reinforces the validity of the paradigm.

1.6 Roadmap

This thesis gives the reader everything that is needed to use the oscilloscope and exploit it to its full potential.

We divided the thesis in multiple chapters:

- Chapter 2 gives the reader a background of the theoretical foundations of ΔQSD , which are the basis of the oscilloscope and are fundamental to understand what is shown in the oscilloscope. Secondly, an introduction to OpenTelemetry, the framework our Erlang adapter is built on top of. Lastly, we provide what we believe are the current limitations of the observability framework and how we plan to tackle them.
- Chapter 3 first provides the “measurement concepts”. These concepts serve as an introduction to understand the following chapters and as a bridge from OpenTelemetry to the oscilloscope. We then delve on how the different parts of our design interact together and how to correctly apply the concepts we introduced. Lastly, after having introduced the oscilloscope, we explain abstract concepts implemented in it, like sliding windows and triggers.
- Chapter 4 & 5 present the oscilloscope. First providing “user level concepts” of how ΔQSD is used and what the user should expect visually from the dashboard. Chapter 4 also provides a complete explanation of how to write outcome diagrams

and what the different sections on the dashboard do. Secondly, in Chapter 5, we give a more low level explanation, which goes into more technical details of the parts that compose the oscilloscope. Namely, we provide mathematical explanations of Δ QSD concepts explained in the previous chapter.

- Chapter 6 provides synthetic applications which have been tested with the oscilloscope that demonstrate the usefulness of the oscilloscope in a distributed setting. In Chapter 7 we perform evaluations of the performance of the different parts we have developed to understand the overhead that are present.

Chapter 8 provides future possibilities which can be explored to improve the application. In the appendix, we provide screenshots of the application. We also provide a user manual to help users use the oscilloscope, along with C++ and Erlang source code of the oscilloscope and the adapter.

The oscilloscope (<https://github.com/fnieri/DeltaQOscilloscope>) and adapter (https://github.com/fnieri/dqsd_otel) can be found on GitHub as open source projects.

Chapter 2

Background

This chapter aims to provide firstly a background of the concepts key to understanding the Δ QSD paradigm.

Secondly, we explain the observability solutions that have been explored for the oscilloscope, delving deeper into OpenTelemetry and its macros.

We finish by explaining what we believe are the current limitations of OpenTelemetry and explaining where the paradigm and the oscilloscope comes in.

2.1 An overview of Δ QSD

Δ QSD is defined as [10]:

“A metrics-based, quality-centric paradigm that uses formalised outcome diagrams to explore the performance consequences of design decisions”.

The key concepts that give the paradigm its name are **quality attenuation** (Δ Q) and **outcome diagrams**. [8]

The dependency and causality properties of a system can be captured by outcome diagrams, while the probability distribution representation (Δ Q) can precisely model a system’s behaviour. [10]

The following sections are a summary of multiple articles and presentations formalising the paradigm. Some of the graphs we present have too been adapted from the articles.

2.1.1 Outcome

To build outcome diagrams, we need to first introduce outcomes.

Outcomes represent system behaviours or tasks that “can start at some point in time and *may* be observed to complete at some later time” [11]. The result produced by performing a system’s task is mapped to an outcome. [10]

The particularity of outcomes is that they can represent multiple levels of granularity. Suppose an outcome is beyond the current system’s control (e.g. a database/cloud

request), is non-atomic (can be broken down in multiple sub-outcomes). These outcomes can be represented as black boxes: you can observe their start and end, but do not know what is being executed. As the system gets refined, these outcomes can then be refined to model a single outcome or multiple outcomes, if needed. [10]

Even though these outcomes are defined as “black boxes”, they still have timeliness constraints like any other outcome.

Let us define some important concepts about outcomes.

Observables Key to outcomes is the notion of event.

An outcome has observable starting events and ending events [8]. As the events may occur in different locations in a distributed setting, we say the outcome has a starting set and ending set of events. They are called “**observables**”. [10]

We stated previously that an outcome **may** be observed to complete, this is because a starting event has no guarantee that it will be ended. An outcome can be said “done” if an end event occurs for a start event.

Outcome instance An outcome instance is the result of an execution of an outcome given a starting event e_{in} and an end event e_{out} . [14]

Graphical Representation Outcomes are represented as circles, with the starting and terminating set of events being represented by boxes. [10]

Figure 2.1: The outcome (circle) and the starting set (left) and terminating set (right) of events.

2.1.2 Failure semantics

Failure indicates “an input message m_{in} **that has no output message** m_{out} ” [14]. It models the probability that the delay is infinite.

2.1.3 Quality attenuation (ΔQ)

ΔQ is defined as “a cumulative distribution function (CDF) that defines both *latency* and *failure probability* between a start and end event”. [8]

As multiple instances of an outcome are executed, multiple delays can be observed for the executions. The observed delays can be represented as a CDF, we call it ΔQ_{obs} . In the ΔQ ’s CDF, $\Delta Q(x)$ is the probability that an outcome O occurs in time $t \leq x$ [14]. We may sometimes use the derivative of a ΔQ , which is the probability density function (PDF). We show a typical CDF of a ΔQ in Fig. 2.2.

The key feature that makes ΔQ stand out is the notion of failure incorporated in the representation of an outcome's behaviour.

Ideally, a system would execute without errors, failure or delay. This is never the case. Since the ideal cannot be attained, the quality of the system's responses are “*attenuated to the relative ideal*” [10]. This quality attenuation gives the name to ΔQ .

Since multiple factors can influence the delays of a response (geographical, physical) [8], ΔQ can be firstly modeled as a random variable. Nevertheless, as it incorporates failures, which are discrete variables, and delays, which are continuous variables, the authors describe it as an Improper Random Variable, as the probability of a finite or bounded delay is < 1 . [10]

Intangible mass Depicted in Fig. 2.2, the *intangible mass* $1 - \lim_{x \rightarrow \infty} \Delta Q(x)$ of a ΔQ encodes the probability of failure/timeout/exception occurring [14].

Figure 2.2: ΔQ CDF representation with intangible mass (red). The failure rate is about 5%

2.1.4 Partial ordering

We say ΔQ_1 is *less than* another ΔQ_2 if its CDF is everywhere to the left and above the other's CDF. This concept is represented mathematically as a partial order. [8]

2.1.5 Timeliness

Timeliness is “delivering results within required time bounds (sufficiently often)”. [8]

2.1.6 QTA, required ΔQ

The Quantitative Timeliness Agreement (QTA) specifies the precise timeliness requirements (ΔQ_{req}) of a ΔQ_{obs} . [11] [14]

Leveraging the definition of partial ordering and timeliness, we can say that a system *satisfies timeliness* if $\Delta Q_{obs} \leq \Delta Q_{req}$. [14]

Slack and hazard There is performance *slack* when “a ΔQ is strictly less than the requirement.” ($\Delta Q_{obs} < \Delta Q_{req}$).

There is performance *hazard* when “an observed ΔQ_{obs} intersects or is strictly greater than the required ΔQ_{req} ” ($\Delta Q_{obs} \not< \Delta Q_{req}$). [10]

QTA example : Imagine a system where 25% of the executions should take < 15 ms, 50% < 25 ms and 75% < 35 ms, all queries have a maximum delay of 50ms and 5% of executions can timeout, the QTA can be represented as a step function.

We present in Fig. 2.3 an example of systems showing slack and hazard.

Figure 2.3: The system in blue is showing slack and satisfies the requirement. The system in orange is showing signs that it cannot handle the stress, it is not respecting the system requirements imposed by the QTA. It intersects with the QTA in p_1, p_2 , so it is not respecting the timeliness requirements. There is performance hazard.

2.1.7 Outcome diagram

An outcome diagram is central to capture the causal relationships between the outcomes [10]. It shows the causal connections between all the outcomes we are interested in. Given an outcome diagram, one can compute the ΔQ for the whole system.

There are four different operators that represent the relationships between outcomes. [8]

Sequential composition

If we assume two outcomes O_A, O_B where the end event of O_A is the start event of O_B , then we say the two outcomes are sequentially composed. The total delay ΔQ_{AB} is given by the convolution of the PDFs of O_A and O_B ($O_A \otimes O_B$).

Figure 2.4: Sequential composition of O_A and O_B .

Where convolution (\otimes) between two PDF is:

$$PDF_A \otimes PDF_B(t) = PDF_{AB}(t) = \int_0^t PDF_A(\delta) \cdot PDF_B(t - \delta) d\delta \quad (2.1)$$

Thus, ΔQ_{AB} :

$$\Delta Q_{AB} = \int_0^t PDF_A \otimes PDF_B d\delta \quad (2.2)$$

Convolution is the only operation which is based on the PDFs, the following operations are based on the CDF of the ΔQ s (hence the use of the ΔQ notation).

First to finish (FTF)

If we assume two independent outcomes O_A, O_B with the same start event, first-to-finish occurs when at least one end event occurs, it can be calculated as:

$$\begin{aligned} (1 - \Delta Q_{FTF(A,B)}) &= Pr[d_A > t \wedge d_B > t] \\ &= Pr[d_A > t] \cdot Pr[d_B > t] = (1 - \Delta Q_A) \cdot (1 - \Delta Q_B) \\ \Delta Q_{FTF(A,B)} &= \Delta Q_A + \Delta Q_B - \Delta Q_A \cdot \Delta Q_B \end{aligned} \quad (2.3)$$

Figure 2.5: Left: $\Delta Q_{(A,B)}$. Right: $FTF_{(A,B)} = \Delta Q_{AB}$

All to finish (ATF)

If we assume two independent outcomes O_A, O_B with the same start event, all-to-finish occurs when both end events occur, it can be calculated as:

$$\begin{aligned} \Delta Q_{ATF(A,B)} &= Pr[d_A \leq t \wedge d_B \leq t] \\ &= Pr[d_A \leq t] \cdot Pr[d_B \leq t] = \Delta Q_A \cdot \Delta Q_B \\ \Delta Q_{ATF(A,B)} &= \Delta Q_A \cdot \Delta Q_B \end{aligned} \quad (2.4)$$

 Figure 2.6: Left: $\Delta Q_{(A,B)}$. Right: $ATF_{(A,B)} = \Delta Q_{AB}$

Probabilistic choice (PC)

If we assume two possible outcomes O_A and O_B and exactly one outcome is chosen during each occurrence of a start event and:

- O_A happens with probability $\frac{p}{p+q}$
- O_B happens with probability $\frac{q}{p+q}$

$$\Delta Q_{PC}(A, B) = \frac{p}{p+q} \Delta Q_A + \frac{q}{p+q} \Delta Q_B \quad (2.5)$$

Figure 2.7: Graphical representation of the possible operators in an outcome diagram. From the left: Probabilistic choice, first-to-finish, all-to-finish [10]

First-to-finish, All-to-finish and probabilistic-choice are calculated on the CDF of the ΔQ s of their components.

These operators can be assembled together to create an outcome diagram. In Chapter 4 we will see how one can go from the graphical representation to outcome diagrams which can be used in the ΔQ oscilloscope.

2.1.8 Outcome diagrams refinement

An important feature of outcome diagrams is the ability to be able to design a system even with “*black boxes*”, before the complete details of it are known. [10]

An outcome diagram can be “unboxed” by refining the outcomes that compose it. We can adapt a situation described by the previously cited article, called “Mind your Outcomes”, to understand how refinement can allow the user to have a very precise representation of a system.

We first start with a black box, unnamed outcome with start event A and end event Z , somewhere in the system. The first refinement step would be giving the outcome a name.

Figure 2.8: Refinement from black box to named outcome.

The system can be further refined by adding outcomes that represent tasks. For example, the engineer might believe that it will take two tasks to get from A to Z . We can then add another outcome, sequentially composed, to represent this situation.

Figure 2.9: Further refinement from one task to two tasks.

We can also model the chance of executing two tasks as a probabilistic choice, where there is p_2 probability that the execution from A to Z will execute two tasks. The outcome diagram can be refined as a probabilistic choice.

Figure 2.10: Refinement as probabilistic choice of executing either one or two tasks.

In essence, the refinement could model a very fine-grained representation of the system by further refining the system, to represent the possibility of executing n tasks. This demonstrates the power of outcome diagrams to represent system diagrams with high precision. They can help explore design decisions thanks to outcomes and operators.

2.1.9 Independence hypothesis

An important aspect of sequential composition is the assumption of outcomes having independent behaviour [13]. Let us explain the following assumption clearly.

Assume the situation described by Section 2.1.9, two sequentially composed outcomes o_1 , o_2 running on the same processor. The overall delay of execution can be observed from the start event of o_1 (u_1) to the end event of o_2 (r_1).

Figure 2.11: Two sequentially composed outcomes, o_1 , o_2 . The end event of o_1 is the start event of o_2 .

At low load, the two components behaviour will be independent (Fig. 2.12), the system will behave **linearly**. According to the superposition principle, the overall delay will be the sum of the two delays, as will the overall processor utilisation. [19]

When load increases, the two components will start to show dependent behaviour due to the processor utilisation increasing. The ΔQ of the observed total delay will then deviate from the sum of the two delays ($o_1 \otimes o_2$). This situation is observed in Fig. 2.12.

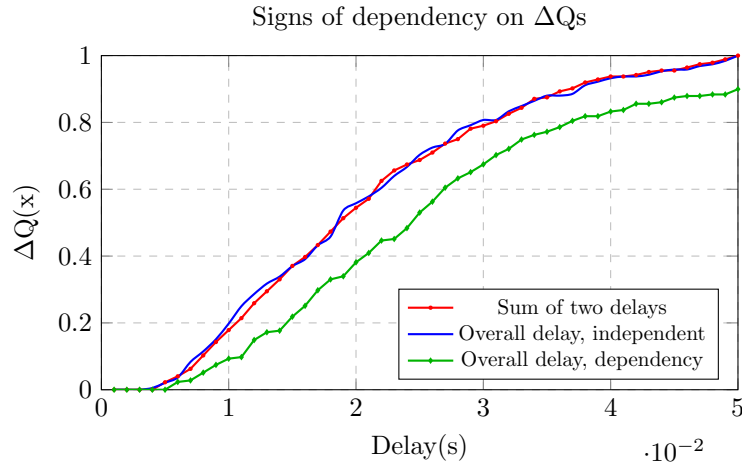

Figure 2.12: When the components are independent, the sum of the two delays (blue) and the overall delay (red) can be superposed. As o_1 and o_2 show signs of dependency, the overall delay (green) can be seen deviating from the sum of the two delays. There is **non-linearity**.

When the system is far from being overloaded, the effect is noticeable. As the cliff edge of overload is approached, the non-linearity will increase [13] [8]. These theoretical results can be observed in the oscilloscope. We will explore such cases in Chapter 6.

2.2 Observability

OpenTelemetry refers to observability as [20]:

“The ability to understand the internal state by examining its output. In the context of a distributed system, being able to understand the internal state of the system by examining its telemetry data.”

In the case of the Erlang programming language, we describe respectively two different ways to observe a running Erlang system: `erlang:trace` and OpenTelemetry.

2.2.1 `erlang:trace`

The Erlang programming language gives the users different ways to observe the behaviour of a system, one of those is the interface `erlang:trace`. According to the documentation: “The Erlang run-time system exposes several trace points that can be observed, observing the trace points allows users to be notified when they are triggered” [17]. One can observe function calls, messages being sent and received, process being spawned, garbage collecting and more.

```
-spec trace(PidPortSpec, How, FlagList) -> integer()
  when
    PidPortSpec ::
      pid() |
      port() |
      all | processes | ports | existing | existing_processes |
      ↪ existing_ports | new |
      new_processes | new_ports,
    How :: boolean(),
    FlagList :: [trace_flag()].
```

Figure 2.13: `erlang:trace/3` specification.

Nevertheless, in Erlang trace there is no default way to follow a message and get its whole execution trace. This is a missing feature that is crucial for observing a program functioning and being able to connect an application to our oscilloscope. This is where the OpenTelemetry framework comes in.

2.2.2 OpenTelemetry

According to OpenTelemetry website [20]: OpenTelemetry is an open-source, vendor-agnostic observability framework and toolkit designed to generate, export and collect telemetry data, in particular traces, metrics and logs. OpenTelemetry provides a standard protocol, a single set of API and conventions and lets the user own the generated data, allowing to switch between observability backends freely.

OpenTelemetry is available for a plethora of languages [21], including Erlang, although, as of writing this, only traces are available in Erlang [22].

The Erlang Ecosystem Foundation has a working group focused on evolving the tools related to observability, including OpenTelemetry and the runtime observability monitoring tools [23].

Traces

Traces are why we are basing our program on top of OpenTelemetry, traces follow the whole path of a request in an application, and they are comprised of one or more spans [5]. Traces can propagate to multiple services and record multiple paths in different microservices [24].

Span A span is a unit of work or operation. Multiple spans can be assembled into a trace and can be causally linked (Fig. 2.15). The spans can have a hierarchy, where *root spans* represent a request from start to finish and a child span the requests that are completed inside the root span [24]. We will see in later sections how this can relate to what the oscilloscope does.

The notion of spans and traces allows us to follow the execution of a request and carry a context. Spans can be linked to mark causal relationships between multiple spans [5]. This relation can be represented in the oscilloscope via **probes**, we will present how spans relate to probes in following sections.

```
{
  "name": "oscilloscope-span",
  "context": {
    "trace_id": "5b8aa5a2d2c872e8321cf37308d69df2",
    "span_id": "5fb397be34d26b51"
  },
  "parent_id": "051581bf3cb55c13",
  "start_time": "2022-04-29T18:52:58.114304Z",
  "end_time": "2022-04-29T22:52:58.114561Z",
  "attributes": {
    "http.route": "some_route"
  },
}
```

Figure 2.14: Example of span from the OpenTelemetry website [5]. The span has a parent, indicating that child and parent spans are related and are both part of the same trace.

Monitoring OpenTelemetry spans

In OpenTelemetry, the user can export their traces export to backends and monitoring such as Jaeger (Fig. 2.15), Zipkin, Datadog [25]. There, a user can analyse the traces to troubleshoot their programs by observing the flow of the requests [26]. These monitoring tools give extensive details about a running system, but may fail to capture essential timeliness requirements and performances issues early enough.

Our oscilloscope is a kind of monitoring tool, one that gives precise statistical insights about a running system. It is clear that the oscilloscope does not have the same capabilities as Datadog [27] might have, where you can observe cloud instances, instances cost, dependency graphs. But the oscilloscope can nevertheless provide precise insights about dependency, overload thanks to the Δ QSD paradigm.

This is also the reason why the adapter includes OpenTelemetry macros. The oscilloscope can be put next to a monitoring tool where one might export spans to, so that an engineer might consult the monitoring tool to get the global picture of a running app, as the oscilloscope can provide more precise insights to understand the system’s behaviour.

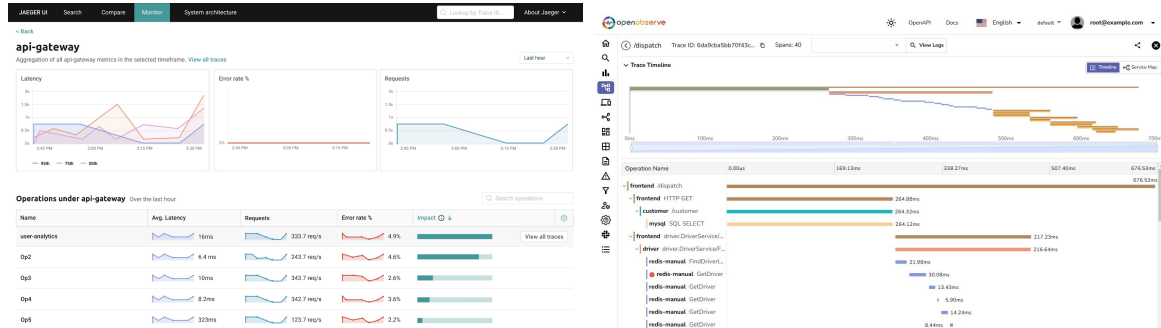

Figure 2.15: **Left:** Jaeger interface [28]. **Right:** Analysis of a span on OpenObserve. [29]

Span macros

OpenTelemetry provides macros to start, end and interact with spans in Erlang, the following code excerpts are taken from the OpenTelemetry instrumentation wiki. [22]

?with_span `?with_span` creates active spans. An active span is the span that is currently set in the execution context and is considered the “current” span for the ongoing operation or thread. [30]

```
parent_function() ->
    ?with_span(parent, #{}, fun child_function/0).
child_function() ->
    %% this is the same process, the span parent set as the active
    %% span in the with_span call above will be the active span in this
    ↪ function
    ?with_span(child, #{},
                fun() ->
                    %% when this function returns, child will complete.
                    end).
```

?start_span `?start_span` creates a span which isn’t connected to a particular process, it does not set the span as the current active span.

```
SpanCtx = ?start_span(child),
Ctx = otel_ctx:get_current(),
proc_lib:spawn_link(fun() ->
    otel_ctx:attach(Ctx),
    ?set_current_span(SpanCtx),
    ?end_span(SpanCtx)
end),
```

`?end_span` `?end_span` ends a span started with `?start_span`

2.3 Current observability problems

The problem we are trying to tackle can be described by the following situation: Imagine an Erlang application instrumented with OpenTelemetry. Suddenly, the application starts slowing down, and the execution of a function takes 10 seconds. The engineer knows it should take at most 1 second. Between its start and its end, no information about the span appears on the dashboard.

We believe that this is a problem. One would like to know right away if something is wrong with their application. This is where the Δ QSD paradigm and the Δ Q oscilloscope come in handy.

Using Δ QSD, we can set a maximum delay (*dMax*) for a task. As soon as the maximum delay is hit, the oscilloscope is notified right away that there is a problem.

Figure 2.16: Execution of a span in OpenTelemetry. Normally, the user will be notified after 10 seconds that the function has ended. The *dMax* deadline gives an early notification that the span has taken too long.

2.3.1 Handling of long spans

OpenTelemetry presents a bigger problem, what happens when there are long-running spans? Even worse, what happens when spans are not actually terminated?

An article has already tackled this problem [21]. In the article it is stated that OpenTelemetry limits the length of its spans, moreover, those who are not terminated are lost and not exported.

In addition, it is said that if the span is the parent/root span, its effect could trickle down to child spans. We can quickly see how this can become problematic, all the information about an execution of your task is lost. A span can apparently not be terminated for trivial reasons: refreshing a tab, network failures, crashes. The author states that there are a few solutions that can be implemented: having shorter spans, carrying data in child spans, saving spans in a log to track spans which were not ended to manually set an end time. The solutions have been implemented by the Embrace (commercial) monitoring tool [31], but it is apparently the only tool out of the ecosystem of monitoring tools.

We believe that the adapter we provide can be a great start to improve observability requirements surrounding OpenTelemetry. Data about spans will always be carried to the oscilloscope, whether the span is long or non-terminated. This is further developed in Chapters 3 & 5.

Chapter 3

Design

This chapter aims to first extend the concepts of Δ QSD, giving more insights into how the different parts of the system need to be instrumented to correctly work together.

- We first provide concepts of probes, we extend the Δ QSD notion of failure and describe how time series will work in our oscilloscope, this part is crucial to understand how the measurements are done in real time.
- We then explain the global design of the system (see Fig. 3.1) in two parts:
Firstly, we explain the application side, where the Erlang running system is. Consequently, it's where the Δ Q adapter interface will be. It performs the translation of spans to outcome instances thanks to the inserted probes.
Secondly, the oscilloscope side. There, the server receives information about outcome instances from the adapter. The Δ Q oscilloscope can then plot Δ Q graphs from the received instances. In the oscilloscope one can define outcome diagrams, set parameters for probes and control the adapter.
- Lastly, we provide high level concepts of execution windows, triggers and snapshot. These are the key design elements of the oscilloscope.

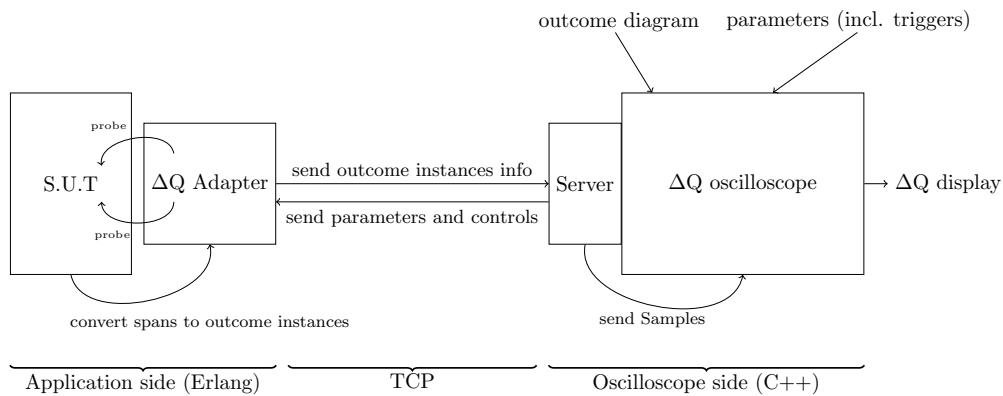

Figure 3.1: Global system design diagram. The two sides communicate via TCP sockets to share information about outcome instances and probe parameters.

3.1 Measurement concepts

3.1.1 Probes

A system instrumented with OpenTelemetry has spans and traces to observe the execution of an operation [5]. The same level of observability must be assured in the oscilloscope, this is why we provide the concept of probes, which, like spans, follow an execution from start to end. **Note** that a definition of probes has already been introduced in a previous article related to ΔQSD [11], but the concept we present here is not the same.

To observe a system, we must put probes in it. For each outcome of interest, a probe (observation point) is attached to measure the delay of the outcome, like one would in a true oscilloscope [13].

Consider Fig. 3.2 below. A probe is attached at every component (for example, a database [8]) to measure their ΔQ s (p_2, p_3). Another probe (p_1) is inserted at the beginning and end of the system to measure the global execution delay. Thanks to this probe, the user can observe the ΔQ “observed at p_1 ”, which is the ΔQ which was calculated from the data received by inserting probe p_1 . The ΔQ “calculated at p_1 ” is the resulting ΔQ from the convolution of the observed ΔQ s at c_2 and c_3 .

Probe p_1 is the equivalent of a “root/parent span” which observe the whole execution of c_1, c_2 . p_2 and p_3 are child spans which represent single tasks.

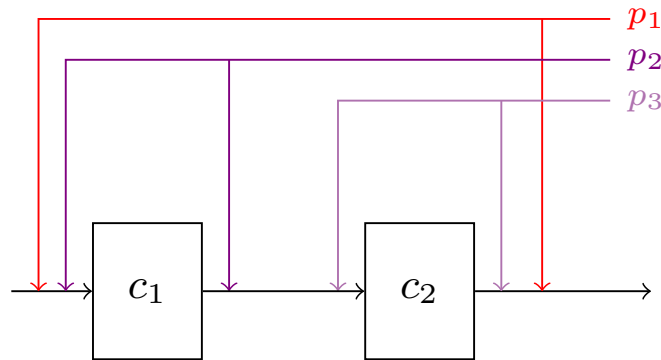

Figure 3.2: Probes inserted in a component diagram. In an application instrumented with OpenTelemetry, p_1 could be considered the root span, c_1 and c_2 its children spans sharing a causal link.

3.1.2 Extending failure

Recall the definition of failure (Section 2.1.2): “an input message m_{in} that has no output message m_{out} ”. We also introduced the notion of a maximum delay (Fig. 2.16). The notion of failure is extended to the following definition:

“An input message m_{in} that has no output message m_{out} after $dMax$ ”

By extending the notion of failure to include $dMax$, we can know right away when execution is straying away from engineer defined behaviour, avoiding having to wait

until the execution is done. In Δ QSD, an execution may as well take 10 or 15 seconds, but if the delay of execution is $> dMax$, we consider that **failed** right away, we do not need to know the total execution time, the execution has already taken too much [10]. The adapter does not interfere with OpenTelemetry, the full span will be exported regardless to monitoring tools which were set up by the user.

The user can observe both real time information with Δ QSD notion of failure on the Δ Q oscilloscope, and observe those spans in their monitoring tools if they wish.

3.1.3 Time series of outcome instances

Consider a probe p with two distinct sets of events, the starting set of events s and ending set of event e . The outcome instance of a message $m_s \rightarrow m_e$ contains:

- The probe's p name.
- The start time t_s .
- The end time t_e .
- Its status.
- Its elapsed time of execution.

The instance has three possible statuses: **success**, **timeout**, **failure**. It can thus be broken down in three possible representations, based on its status:

- (t_s, t_e) : This representation indicates that the execution was successful ($t < dMax$).
- (t_s, \mathcal{T}) : This representation indicates that the execution has timed out ($t > dMax$). The end time is equal to $t_s + \text{timeout}$.
- (t_s, \mathcal{F}) : This representation indicates the execution has failed given a user defined requirement (i.e. a dropped message given buffer overload in a queue system). It must not be confused with a program failure (crash), if a program crashes during the execution of event e , it will time out since the adapter will not receive an end message.

The **time series** of a probe is the sequence of n outcome instances. The collected elapsed times of execution (delays) from the outcome instances can be represented as a CDF, which is a Δ Q.

What can be considered a failed execution? The choice of what is considered a failed execution is left up to the user who is handling the spans and is program-dependent. Exceptions or errors can be kinds of failure.

Imagine a queue with a buffer: the buffer queue being full and dropping incoming messages can be modeled as a failure.

On another note, the way of handling “errored” spans in OpenTelemetry can differ from user to user [32], so the adapter will not handle ending and setting statuses for “failed” spans.

In any case, **timed out and failed will both be considered as a failure** in a ΔQ . The distinction in an outcome instance is there for future refinements of the oscilloscope, where more statistics can be displayed about a ΔQ .

3.2 Application side

3.2.1 System under test

The system under test (**S.U.T**) is the Erlang system the engineer wishes to observe (Fig. 3.1). It ideally is a system which already is instrumented with OpenTelemetry. The ideal system where ΔQSD is more useful is a system that executes many independent instances of the same action [8].

3.2.2 ΔQ Adapter

The ΔQ adapter is the `dqsd_otel` Erlang interface [33]. It starts and ends OpenTelemetry spans and translates them to outcome instances which are useful for the oscilloscope. This can be done thanks to probes being attached to the system under test, like an oscilloscope would. The outcome instances end normally like OpenTelemetry spans or, additionally, can timeout after a custom timeout (*dMax*), and fail, *according to user's definition of failure*.

Handling of OpenTelemetry spans which goes beyond starting and ending them is delegated to the user, who may wish to do further operations with their spans. The adapter is called from the system under test and communicates outcome instances data to the oscilloscope via TCP sockets.

The adapter can receive messages from the oscilloscope, the messages are about updating probe's *dMax* or starting and stopping the sending of data to the oscilloscope.

3.2.3 Inserting probes in Erlang - From spans to outcome instances

OpenTelemetry spans are useful to carry context, attributes and baggage in a program [24]. The plethora of attributes they have is nevertheless too much for the oscilloscope. To get the equivalent of spans for the oscilloscope, the adapter needs to be called at the starting events of a probe to start an instance of a probe, and at the ending events to end the outcome instance. The name given with "`start_span/with_span`" is the name of the probe. The PID which is returned by starting a span must be carried throughout the whole execution, and used when ending spans to create the correlation between a probe and an outcome instance.

```

% Start the outcome instance of probe. The call to dqsd_otel starts an
→ OpenTelemetry span, as it contains a call to ?start_span(Name)
{ProbeCtx, ProbePid} = dqsd_otel:start_span(<<"probe">>),

% Start and fail span directly
{WorkerCtx, WorkerPid} = dqsd_otel:start_span(<<"worker_1">>),
dqsd_otel:fail_span(WorkerPid),
%Here, you would need to end the span manually with ?end_span

%Example of with_span, the call to OpenTelemetry ?with_span is inside
→ the adapter function, the function fun() -> ok end is executed
→ inside dqsd_otel.
dqsd_otel:with_span(<<"worker_2">>, fun() -> ok end),
%End the outcome instance of probe. This ends the OpenTelemetry span
→ aswell. If the outcome instance has already timed out (the time
→ from start_span to end_span > dMax), the oscilloscope receives no
→ message where the status is successful. Otherwise, this sends a
→ message with startTime, endTime, the name "probe" and success
→ status.
dqsd_otel:end_span(ProbeCtx, ProbePid),

```

Figure 3.3: Example usage of the adapter

Further details about the implementation of the adapter are explained in Chapter 5. A user guide on how to include the adapter in your project and how to instrument a program is found in the appendix (Section D.6).

3.3 Oscilloscope side

3.3.1 Server

The server is responsible for receiving the messages containing the outcome instances from the adapter. The server forwards the instances to the oscilloscope.

3.3.2 ΔQ Oscilloscope

The oscilloscope is a C++ graphical application which implements a dashboard to observe ΔQ s of probes inserted in the system under test [34]. It receives the instances corresponding to probes from the server and adds them to the time series of the probes whose instance is being received. The oscilloscope has a graphical interface which allows the user to create an outcome diagram of the system under test, display real time graphs which show detail about the execution of the system, and allows the user to set parameters for probes. It can also display snapshots of the system as if it was frozen in time.

3.3.3 Inserting probes in the oscilloscope

Probes are automatically inserted in the oscilloscope when creating outcome diagrams. They are inserted on the outcomes observables, operators observables and to the sub-outcome diagrams observables (probes that observe the causal links of multiple outcomes/operators), we will see later on how they can be defined and how an outcome diagram can be created.

The names that are given to outcome, operators and sub-outcome diagrams are the names of the probes that observe them. Giving these probes a name allows the oscilloscope to match the outcome instances received by the adapter to the probes' time series.

In the system below (Fig. 3.4), which is equal to the one defined previously (Fig. 3.2), probes are automatically attached to outcomes o_1, o_2 . The user who wants to observe the result of the sequential composition can insert probes at the start and end of the routine.

Figure 3.4: Probes inserted in the outcome diagram of the previous component diagram in Fig. 3.2.

The **observables** are an abstract representation of events. Consider the previous code snippet Fig. 3.3: the *start* event of “probe” and *worker₁*’s start event are subsequent instructions. The probe’s start event is practically the same as *worker₁*’s start event, indeed, they could be overlapped in the graph above (Fig. 3.4). We nevertheless show the distinction to show that probe and *worker₁* need to be started differently in Erlang as the information they carry is about two distinct instances. It is the same concept as starting a parent/child span. Furthermore, this difference is remarked in the definition of outcome diagrams for the oscilloscope, for which we provide a syntax in the Chapter 4.

As for operators, probes are automatically attached to the components inside them and to the operators’ observables (Section 3.3.3).

Figure 3.5: Probes inserted into an operator.

The **observed** ΔQ for the first-to-finish operator is the ΔQ for the observables (**start**, **end**). The **calculated** ΔQ is the ΔQ which is the result of the first-to-finish operator being applied on o_1, o_2 .

3.4 Sliding execution windows

There are two important windows that we consider in our oscilloscope, the *sampling window* and the *polling window*.

3.4.1 Sampling window

Suppose we are at time t , the observed ΔQ of a sampling window at time t we display is the ΔQ obtained from the outcome instances who ended within a **window of time** $(t-1)_l - (t-1)_u$, with $(t-1)_u$ equal to $t-x$, and x the sampling rate. The sampling rate x is how often ΔQ s are calculated.

This is to account for various overheads that need to be taken into consideration. They could be network overheads, the adapter overhead, C++ latency and more. Imagine multiple outcome instances that are ended at a time slightly lower but close to t , and due to the overheads the messages arrive at a time slightly higher but close to t , the outcome instance would not be taken into consideration for the calculation of a ΔQ .

The sampling window then advances every x seconds, setting the new window:

$$\begin{aligned} &\text{From: } (t-1)_l, (t-1)_u \xrightarrow{t+1} t_l, t_u. \\ &\text{Where: } t_l = (t-1)_u \text{ and } t_u = (t-1)_u + x \end{aligned}$$

The ΔQ s which are observed and calculated in a sampling window are not precise, this is why we need to introduce the polling window.

3.4.2 Polling window (Observing multiple ΔQ s over a time interval)

The polling window is the window of past ΔQ s which are stored to keep a snapshot of the system over time and over which confidence bounds are calculated. The polling window serves to improve the precision of the ΔQ measurement.

Suppose we are at time $t = 0$, the polling window will have 0 ΔQ s. As the sampling window advances, more ΔQ s are sampled, which in turn are added to the polling window, to the snapshot, and to the confidence bounds.

The limit of ΔQ s for a polling window (subsequently snapshots and confidence bounds) is 30 ΔQ s. At $t = 31$, the older ΔQ s will be removed from the polling window and in turn from the confidence bounds. Newer sampled ΔQ s will be added, keeping the limit of ΔQ s in a polling window to 30.

3.5 Triggers

Much like an oscilloscope that has a trigger mechanism to capture periodic signals or investigate a transient event [35], the ΔQ *oscilloscope* has a similar mechanism that can recognise when an observed ΔQ violates certain conditions regarding required behaviour and record snapshots of the system.

Each time an observed ΔQ of a sampling window is calculated, it is checked against the requirements set by the user. If these requirements are not met, a trigger is fired and a snapshot of the system is saved to be shown to the user.

3.5.1 Snapshot

A snapshot of the system gives insights into the system before and after a trigger was fired. It gives the user a *still* of the system, as if it was frozen in time. All the ΔQ s which are observed and calculated in a polling window are stored away. Then, if no trigger is fired, older ΔQ s are removed, both from the polling window and from the snapshot.

Instead, if a trigger is fired, the oscilloscope keeps recording ΔQ s without removing older ones, to allow the user to look at the state of the system before and after the trigger. The snapshot keeps recording for 5 seconds, after these 5 seconds the snapshot can be viewed by the user. The polling window size stays fixed, while the snapshot size increases during the recording of one. When the snapshot has finished recording, their windows sizes align.

Chapter 4

Oscilloscope: User level concepts

The following chapter gives insights on the user level concepts of Δ QSD in the oscilloscope. They are the concepts needed by the user to understand how the oscilloscope works.

- We first provide insights into how the concepts related Δ QSD are implemented in the oscilloscope, the parameters that define a probe's Δ Q, its representation. We show how probe's Δ Q(s) will be shown in the oscilloscope.
- We then provide a language to write outcome diagrams based on an already existing syntax and provide an example.
- Lastly, we explain the different widgets on the oscilloscope dashboard and the available triggers.

4.1 Δ QSD concepts

We provide in this section the concepts needed to understand what is displayed on the oscilloscope.

4.1.1 Representation of a Δ Q

We provide a class to calculate the Δ Q of a probe in a sampling window between a lower time bound t_l and an upper time bound t_u . It can be calculated in two ways:

Observed Δ Q The first way is by having n collected outcome instances whose end time is between t_l and t_u , calculating the PDF of the delays of the outcome instances, and calculating the resulting CDF based on the PDF. This is called the **Observed Δ Q**.

Calculated Δ Q A Δ Q can also be calculated by performing operations on two or more observed Δ Qs (convolution, operators operations), the notion of outcome instances is lost between calculations, as the interest shifts towards calculating the resulting PDFs

and CDFs. This is called the **Calculated ΔQ** . A simple outcome can **not** have a “calculated ΔQ ”, we can only observe the delay from its observables.

If you recall Fig. 3.4, the probes o_2 and o_3 observe simple outcomes, they can only display the observed ΔQ s of o_2, o_3 . The probe p_1 instead observes the sequential composition of said outcomes. We can display its “observed ΔQ ” from the execution from *start* to *end* and the “calculated ΔQ ” as the convolution of the observed ΔQ s of o_1, o_2

Figure 4.1: (Red, circle, above): Sampling window **Calculated ΔQ** . (Blue, diamond, below): Sampling window **Observed ΔQ**

4.1.2 $dMax = \Delta t \cdot N$

The key concept of ΔQSD is having a maximum delay after which we consider that the execution is timed out. This is represented in the oscilloscope as $dMax$. Understanding this equation is key to correctly using the oscilloscope and exploring tradeoffs

Let us explain the following equation:

$$dMax = \Delta t \cdot N \quad (4.1)$$

- $dMax$: The maximum delay, it represents the maximum delay that an outcome instance of a probe can have. The execution is considered “timed out” (failure) after $dMax$.
- Δt : The resolution of a ΔQ . It is the bin width of a bin in a probe’s ΔQ .
- N : The precision of a ΔQ . It is the number of bins in a probe’s ΔQ .

It can be informally described as a “two out of three” equation. If the user wants higher precision but the same $dMax$, the resolution must change, and so on for every parameter.

Figure 4.2: Left: Sample ΔQ representation as a histogram with higher resolution but lower precision.
 Right: Sample ΔQ representation as a histogram with lower resolution but higher precision.
 Both ΔQ s have the same $dMax$, but the amount of precise information they provide is far different.

Setting a maximum delay for a probe is not a job that can be done one-off and blindly, it is something that is done with an underlying knowledge of the system inner-workings and must be thoroughly fine-tuned during the execution of the system by observing the resulting distributions of the obtained ΔQ s.

Some tradeoffs must though be acknowledged when setting these parameters, a higher number of bins corresponds to a higher number of calculations and space complexity, a lower $dMax$ may correspond to more failures. The user must set these parameters carefully during execution.

Figure 4.3: $\Delta Q: dMax = 50ms$, the ΔQ will stay constant when delay $> dMax$.

dMax limitation

$dMax$ can **not** be lower than 1 millisecond and will be rounded to the **nearest** integer in the adapter, this is a limitation of Erlang `send_after` function which only accepts

integers and milliseconds values. For example, if on the oscilloscope the $dMax$ is equal to $1.56ms$, the adapter will fail spans after 2 ms.

4.1.3 QTA

A simplified QTA is defined for probes. We define 4 points for the step function at 25, 50, 75 percentiles and the minimum percentage p of successful instances accepted for an observable ($0 < p < 1$). The QTA is comparable to the one we have shown in Fig. 2.3. The user can set the QTAs they want for the probes they have inserted, but the delays at the percentiles must be $< dMax$.

4.1.4 Confidence bounds

To observe the stationarity of a probe we must observe its ΔQ s over a polling window and calculate confidence bounds over said ΔQ s. A single ΔQ may fluctuate. This is why we include the mean and confidence bounds of ΔQ s in the plot, which give a probability range over which the true CDF of the ΔQ should fall. [36]

Confidence bounds are given for *observed* and *calculated* ΔQ s in a polling window (Fig. 4.4).

We first calculate a mean of the ΔQ s in the polling window, this gives an idea of how the probe has been behaving during the polling window. Given this mean, we can calculate its confidence bounds.

The bounds are updated dynamically by inserting or removing a ΔQ to the current polling window. Every time a new ΔQ is calculated, the oldest ΔQ in a window is removed if $\# \Delta Qs(\text{polling window}) > \text{limit}$. The new ΔQ is added to the calculation of the mean and confidence bounds as it is calculated.

This allows us to consider a small window of execution rather than observing the execution since the start of the system for the bounds. This can help in observing stationarity of the system, where a fewer number of past ΔQ s can help observe short term behaviour.

With a big window of ΔQ s, temporary overload may not greatly affect the mean and bounds, while, if we consider the current size of the polling window (30 ΔQ s), a few ΔQ s which deviate from stationary behaviour have a greater impact on the bounds and mean.

Figure 4.4: Upper and lower bounds (dashed, red) of the mean (blue) of multiple ΔQ s. In a system that behaves linearly, the bounds will be close to the mean, once the overload is approaching, or a system is showing behaviour that diverges from a linear one, the bounds will appear larger.

4.2 ΔQ display

Now that we have introduced the required concepts, we can put everything together to be plotted. In summary, a probe's displayed graph must contain:

- The observed ΔQ of the sampling window, with the mean and confidence bounds calculated over the polling window of observed ΔQ s.
- If applicable, the calculated ΔQ from the causally linked components observed in a probe, with the mean and confidence bounds calculated over the polling window of calculated ΔQ s.
- Its QTA (if defined).

This allows for the user to observe if a ΔQ has deviated from normal execution, analyse its stationarity, non-linearity and observe a single execution over a polling window.

In the photo below (Fig. 4.5) we can observe the multiple elements as they are displayed in real time in the oscilloscope.

- (1): The mean of the polling window observed ΔQ s (yellow) with the confidence bounds of the mean. Upper bound (dark green) and lower bound (light green). The observed ΔQ of the sampling window can be observed going out of the confidence bounds at delay 0.00125 s. The ΔQ in a sampling window is less precise than the mean and confidence bounds calculated in the polling window.
- Arrow, red, above: The mean of the calculated ΔQ s (ochre) with the confidence bounds of the mean. Upper bound (purple) and lower bound (magenta). The calculated ΔQ of the sampling window is inside its confidence bounds.
- (3): The **QTA**.

Figure 4.5: ΔQ s, confidence bounds, means and QTA for a probe observing the causal link of multiple components.

4.3 Outcome diagram

An abstract syntax for constructing outcome diagrams has already been defined in a previous paper [14], nevertheless, the oscilloscope needs a textual way to define an outcome diagram.

We define a grammar to create an outcome diagram in our oscilloscope, which is a textual interpretation of the abstract syntax.

4.3.1 Causal link

A causal link between two components can be defined by a right arrow from `component_i` to `component_j`:

```
component_i -> component_j
```

4.3.2 Sub-outcome diagrams

Multiple sub-outcome diagrams can be created for multiple parts of the system. They can then be linked together to form the global system outcome diagram. Sub-outcome diagrams can observe one or multiple components. Recall Fig. 3.4, we defined a probe which observes the sequential composition of o_1, o_2 . The probe (sub-outcome diagram) p_1 can be defined as:

```
p_1 = o_1 -> o_2;
```

A probe is attached at the start and end events of p_1 , it will observe the whole system and the calculated ΔQ will be the convolution of o_1, o_2 .

The lines defining these diagrams must be semicolon terminated. Outcomes and operators cannot be defined on their own, they must be observed in a sub-outcome diagram.

Sub-outcome diagrams can be reused in other diagrams by adding `s:` (sub-outcome diagram) before they are used.

```
p_3 = s:p_1 -> s:p_2;
```

This allows for easy composition and reuse of different parts of the system, allowing for independent refining of diagrams.

4.3.3 Outcomes

To attach a probe to an outcome observables, it is enough to declare an outcome with its name inside a diagram.

```
... = outcomeName;
```

4.3.4 Operators

First-to-finish, all-to-finish and probabilistic choice operators must contain at least two components.

All-to-finish operator

An all-to-finish operator needs to be defined as follows:

```
a:name(component1, component2...)
```

First-to-finish operator

A first-to-finish operator needs to be defined as follows:

```
f:name(component1, component2...)
```

Probabilistic choice operator

A probabilistic choice operator needs to be defined as follows:

```
p:name[probability_1, probability_2, ... probability_i](component_1,  
  ↪ component_2, ..., component_i)
```

In addition to being comma separated, the number of probabilities inside the brackets must match the number of components inside the parentheses. For n probabilities p_i , $0 < p_i < 1$, $\sum_{i=0}^n p_i = 1$

4.3.5 Limitations

Our system has a few limitations compared to the theoretical applications of ΔQ , namely, no cycles are allowed in the definition of outcome diagrams.

```
p_1 = s:p_2;
p_2 = s:p_1;
```

The above example is not allowed and will raise an error when defined.

4.3.6 Outcome diagram example

We provide a sample example of an outcome diagram definition. We also provide its resulting outcome diagram with probes inserted.

```
two_hops = o2 -> o3;
total = p:pc[0.9, 0.1](o1, s:two_hops);
```

Figure 4.6: Sample textual definition of an outcome diagram.

Figure 4.7: Resulting outcome diagram for definition 4.6.

4.4 Dashboard

The dashboard is devised of multiple sections where the user can interact with the oscilloscope, create the system, observe the behaviour of its components, set triggers.

4.4.1 Sidebar

The sidebar has multiple tabs, we explain here the responsibility of each one.

System/Handle plots tab

In this tab, one can create the outcome diagram, add plots and modify current plots. A photo of the tab can be found in Section B.1.

System creation In this widget the user can create its system with the outcome diagram grammar. They can save the outcome diagram text or load it, the outcome diagram definition is saved to a file with any extension, we nevertheless define an extension to save the system to, the extension `.dq`. If the definition of the input is wrong, they will be warned with a pop-up giving the error the parser generator encountered in the creation of a system.

Adding a plot Once the system is defined, the user can choose the probes they want to plot. They can select multiple probes per plot and display multiple plots on the oscilloscope window.

Sampling rate The user can choose the sampling rate of the system: How often ΔQ s are calculated and displayed in the oscilloscope.

Editing a plot By clicking onto a plot that is being shown, the user can choose to add or remove probes to and from it, thanks to the widget in the lower right corner. Multiple probes can be selected to either be removed or added.

Parameters tab

In this tab, the user can define parameters for the probes they have defined. A photo of this tab can be found in Section B.2.

Set a QTA The user is given the choice to set a QTA for a given probe. They have 4 fields where they can fill in which correspond to the percentiles and the minimum amount of successful instances accepted. They can change this dynamically during execution. If a new $dMax$ is set, where $dMax <$ the defined delays in the QTA, the QTA is reset.

dMax, bins The user can set the parameters we explained previously, Δt and N . When this information is saved by the user, the new $dMax$ is transmitted to the adapter and saved for the selected observable.

Triggers tab

In the triggers tab the user can set triggers and observe the snapshots of the system. A photo of the tab can be found in Section B.3.

Set triggers The user can set which triggers to fire for the probes they desire, they are given checkboxes to decide which ones to set as active or not (by default, the triggers are deactivated).

Fired triggers Once a trigger is fired, the oscilloscope starts a timer for 5 seconds, during which all probes start recording the observed ΔQ s (and the calculated ones if applicable) without discarding older ones. Once the timer expires, the snapshot is saved

for the user in the triggers tab. In the dashboard, it indicates when the trigger was fired (timestamp) and the name of the probe which fired it.

Snapshot window Clicking on a snapshot, a new window opens. The user can explore a frozen state of the system, being able to explore all the ΔQ s saved in a snapshot. A screenshot of the snapshot window is provided in Section B.4.

Connection controls

Here, the user can connect to the Erlang endpoint. They can also start the oscilloscope server to receive outcome instances from the adapter. An image of the tab can be found in Section B.5.

Erlang controls The user can set the IP and the port where the ΔQ adapter is listening from. Two additional buttons communicate with the adapter by sending messages, they can start and stop the adapter's sending of outcome instances.

C++ server controls The user can set the IP and the port for the oscilloscope's server, where it will receive outcome instances from the adapter.

4.4.2 Plots window

To the left, the main window shows the plots of the probes being updated in real time. The window can be seen in Section B.2, Section B.3.

4.5 Triggers

There are two available triggers which can be selected by the user, the triggers are evaluated on the **observed ΔQ** of a sampling window.

Part of future work is extending the available triggers in the oscilloscope. We are aware that the number of available triggers may not seem like much. We believe nevertheless that the triggers we provide are a sufficient basis to observe rare events and detect non-linearity or overload.

4.5.1 Load

A trigger on an observed ΔQ of a *sampling window* can be fired if the amount of outcome instances received for a probe in a sampling window is greater than what the user defines:

$$\#instances_{probe}(\Delta Q) > \maxAllowedInstances_{probe}$$

4.5.2 QTA

A trigger on an observed ΔQ of a *sampling window* can be fired if:

$$\Delta Q_{obs} \not\prec observableQTA$$

Chapter 5

Oscilloscope: implementation

The following chapter gives a more technical description of the internals of the oscilloscope.

- We provide a more in-depth look at the Δ QSD concepts introduced in the previous chapter.
- We then explain how the Δ Q adapter works, its API and the underlying mechanism that let us export outcome instances to the oscilloscope.
- Lastly, we briefly talk about the parser generator used to parse the outcome diagram syntax and the dashboard graphical framework.

5.1 Δ QSD implementation

In this section we provide the mathematical foundations of Δ QSD as they are implemented in the oscilloscope.

5.1.1 Histogram representation of Δ Q

We approximate the probability distribution of Δ Q via histograms.

PDF

We partition the values into N bins of equal width, Given $[x_i, x_{i+1}]$ the interval of a bin i , where $x_i = i\Delta t$, and $\hat{p}(x_i)$ the value of the PDF at bin i , for n bins [37]:

$$\begin{cases} \hat{p}(i) = \frac{s_i}{n}, & \text{if } i \leq n \\ \hat{p}(i) = 0, & \text{if } i > n \end{cases} \quad (5.1)$$

Where s_i the number of successful outcome instances whose elapsed time is contained in the bin i , n the total number of instances.

CDF

The value $x_i = \hat{f}(i)$ of the CDF at bin i with n bins can be calculated as:

$$\begin{cases} \hat{f}(i) = \sum_{j=1}^i \hat{p}(j), & \text{if } i \leq n \\ \hat{f}(i) = \hat{f}(n), & \text{if } i > n \end{cases} \quad (5.2)$$

Figure 5.1: Blue bins: PDF of a sample ΔQ . Red: Resulting CDF of ΔQ PDF, the CDF is what is displayed on the dashboard.

5.1.2 dMax

We introduced $dMax$ in the previous chapters (Eq. (4.1)), we provide here the full equation that allows $dMax$ to be calculated:

$$\begin{aligned} \Delta t &= \Delta t_{base} \cdot 2^n \\ dMax &= \Delta t_{base} \cdot 2^n \cdot N \end{aligned} \quad (5.3)$$

Where:

- Δt_{base} represents the base width of a bin, equal to 1ms.
- n the exponent that is set by the user in the dashboard. It is limited to $[-10, 10]$.
- N the number of bins, it is limited to $[1, 1000]$.

We chose 1 ms in combination with 2^n as it allows us to go from very fine bin widths ($\approx 1 \mu s$) to large bin widths ($\approx 1 s$), thanks to the $[-10, 10]$ bounds. Moreover, scaling by a power of 2 allows all the probe's ΔQ s to have a common factor to perform operations on them after rebinning (Eq. (5.4)).

5.1.3 Rebinning

Rebinning refers to the aggregation of multiple bins of a bin width i to another bin width j [38]. Previous operations between ΔQ s must be done on ΔQ s that have the

same bin width. This is why it is fundamental that all probes have a common Δt_{base} and why we have a 2^n factor to calculate the total bin width.

Given two ΔQ s ΔQ_i , ΔQ_j , the common bin width Δt_{ij} is:

$$\Delta t_{ij} = \max \{ \Delta t_i, \Delta t_j \}$$

The PDF of the rebinned ΔQ at bin b , from the original PDF of n bins, where $\Delta t_i > \Delta t_j$ and $k = \frac{\Delta t_i}{\Delta t_j}$:

$$p'_b = \sum_{n=b-k}^{b+1 \cdot k - 1} p_n, \quad b = 0, 1, \dots, \lceil \frac{N}{k} \rceil \quad (5.4)$$

We perform rebinning to a higher bin width for a simple reason. While this leads to loss of information for the ΔQ with the lowest bin width, rebinning to a lower bin width would imply inventing new values for the ΔQ with the highest bin width.

5.1.4 Convolution

We present the two solutions to perform convolution we explored during the implementation.

Naïve convolution

Given two ΔQ binned PDFs f and g with equal bin widths, the result of the convolution $f \otimes g$ is given by [39]:

$$(f \otimes g)[n] = \sum_{m=0}^N f[m]g[n-m] \quad (5.5)$$

The naïve way of calculating convolution has a time complexity of $\mathcal{O}(N^2)$, this quickly becomes a problem as soon as the user wants to have a more fine-grained understanding of a component. The oscilloscope presented noticeable lag and frame skipping with high resolution. This is why we decided to explore Fast Fourier Transform convolution.

Fast Fourier Transform Convolution

FFTW (Fastest Fourier Transform in the West) is a C subroutine library [40] for computing the discrete Fourier Transform in one or more dimensions, of arbitrary input

size, and of both real and complex data. We use FFTW in our program to compute the convolution of ΔQ s. We adapt our script from an already existing one found on GitHub. [41]

Whilst the previous algorithm is far too slow to handle a high number of bins, convolution leveraging Fast Fourier Transform (FFT) allows us to reduce the amount of calculations to $\mathcal{O}(N \log N)$. This is why the naïve convolution algorithm is not used. We will analyse the time gains in Chapter 7.

FFT and naïve convolution produce the same results in our program, barring ε differences (around 10^{-18}) in bins whose result should be 0. This is most likely due to rounding error.

FFTs algorithms are plenty, the choice of the one to use is left up to the subroutine via the parameter `FFTW_ESTIMATE`. [42]

The explanation of the algorithm is beyond the scope of this master thesis, we refer the reader to the following book as a reference. [43]

5.1.5 Arithmetical operations

The FTF, ATF and PC operators on ΔQ s use a simple set of arithmetical operations to calculate a ΔQ . The time complexity of FTF, ATF and PC is trivially $\mathcal{O}(N)$ where N is the number of bins.

Scaling (multiplication) A ΔQ can be scaled w.r.t. a constant $0 \leq j \leq 1$. It is equal to binwise multiplication on CDF bins. It is used for the probabilistic choice operator.

$$\hat{f}_r(i) = \hat{f}(i) \cdot j \quad (5.6)$$

Operations between ΔQ s Addition, subtraction and multiplication can be done between two ΔQ of equal bin width (but not forcibly of equal length) by calculating the operation between the two CDFs of the ΔQ s:

$$\Delta Q_{AB}(i) = \hat{f}_A(i)[\cdot, +, -] \hat{f}_B(i) \quad (5.7)$$

They are used for all operators.

5.1.6 Confidence bounds

Here is how we calculate the mean and lower/upper confidence for the ΔQ s CDF at bin $i \quad \forall i < N$. [37]

For x_{ij} , the value of an CDF j at bin i , the mean of n CDFs for the bin i in a polling window is:

$$\mu_i = \frac{1}{n} \sum_{j=1}^n x_{ij} \quad (5.8)$$

Its variance:

$$\sigma_i^2 = \frac{1}{n} \sum_{j=1}^n x_{ij}^2 - \mu_i^2 \quad (5.9)$$

The lower confidence bound $CI_{i,l}$ and upper confidence bound $CI_{i,u}$ for a bin i can be calculated as:

$$CI_{i,l} = \mu_i - \frac{\sigma_i}{\sqrt{n}}, CI_{i,u} = \mu_i + \frac{\sigma_i}{\sqrt{n}} \quad (5.10)$$

The confidence bounds for the CDF are the lower and confidence bounds for every bin i .

5.2 Adapter

The adapter, called `dqsd_otel` is a rebar3 [44] application built to replace OpenTelemetry calls and create outcome instances. It is designed to be paired with the oscilloscope to observe an Erlang application.

5.2.1 API

The adapter functions to be used by the user are made to replace OpenTelemetry calls to `?start_span` and `?with_span` and `?end_span` macros. This is to make the adapter less of an encumbrance for the user and to extend the tool usefulness in observing distributed programs.

The adapter will always start OpenTelemetry spans but only start outcome instances if the adapter has been activated. The adapter can be activated by the oscilloscope by pressing the “*start adapter*” button and can be stopped via the “*stop adapter*” button.

start_span/1, start_span/2

```
start_span/1: -spec start_span(binary()) -> {opentelemetry:span_ctx(),
  ↳ pid() | ignore}.
start_span/2: -spec start_span(binary(), map()) ->
  ↳ {opentelemetry:span_ctx(), pid() | ignore}.
```

Parameters:

- **Name:** Name of the probe in Erlang binary representation. For example, if the name of the probe is “probe”, the binary representation would be constructed with “«probe»” [45] [46]. We will refer to this as “binary name” from now on.
- **Attributes:** The OpenTelemetry span attributes (Only for `start_span/2`).

`start_span` incorporates OpenTelemetry `?start_span(Name)` macro.

Return: The function returns either:

- `{SpanCtx, span_process_PID}` if the adapter is active and the probe’s *dMax* has been set.
- `{SpanCtx, ignore}` if one of the two previous conditions was not respected.

With `SpanCtx` being the context of the span created by OpenTelemetry.

with_span/2, with_span/3

```
with_span/2: -spec with_span(binary(), fun(() -> any())) -> any().
with_span/3: -spec with_span(binary(), fun(() -> any()), map()) ->
  ↳ any().
```

Parameters:

- Name: Binary name of the probe.
- Fun: Zero-arity function representing the code of block that should run inside the `?with_span` macro.
- Attributes: The OpenTelemetry span attributes (Only for `with_span/3`).

`with_span` incorporates, thus replaces the OpenTelemetry `?with_span` macro.

Return: `with_span` returns what Fun returns (`any()`).

end_span/2

```
-spec end_span(opentelemetry:span_ctx(), pid() | ignore) -> ok |
  ↳ term().
```

Parameters:

- SpanCtx: The context of the span returned by `start_span`.
- Pid: `span_process_PID` || `ignore`.

`end_span` the OpenTelemetry `?end_span(Ctx)` macro.

fail_span/1

```
-spec fail_span(pid() | ignore) -> ok | term().
```

Parameter:

- Pid: `ignore` || `span_process_PID`.

`fail_span` does not incorporate any OpenTelemetry macro, it is let up to the user to decide how to handle failures in execution.

span_process

`span_process` is the process, spawned by `start_span`, responsible for handling the `end_span`, `fail_span`, `timeout` messages.

Upon being spawned, the process starts a timer with time equal to the *dMax* set by a user for the probe being observed, thanks to `erlang:send_after`. When the timer runs out, it sends a `timeout` message to the process.

The process can receive three kinds of messages:

- `{end_span, end_time}`: This will send an outcome instance to the oscilloscope with the start and end time of the execution of the probe and success status.
- `{fail_span, end_time}`: This will send an outcome status to the oscilloscope indicating that an execution of a probe has failed.
- `{timeout, end_time(StartTime + dMax)}`: If the program hasn't ended the span before *dMax*, the timer will send a `timeout` message. It will send an outcome instance to the oscilloscope indicating that an execution of a probe has timed out.

The `span_process` is able to receive one and only message, if the execution times out and subsequently the span is ended, the oscilloscope will not be notified as the process is defunct. This is assured by Erlang documentation:

If the message signal was sent using a process alias that is no longer active, the message signal will be dropped. [47]

5.2.2 Handling outcome instances

To create outcome instances of a probe we must obtain three important informations:

- Its name.
- The time when the span was started.
- Its *dMax*.

The start time and end time are supplied upon starting/ending a span by calling this function:

```
StartTime/EndTime = erlang:system_time(nanosecond).
```

The name is given when starting a span and the *dMax* is stored in a dictionary in the adapter.

The outcome instance is created only if two conditions are met: the adapter has been set as active and the user set a timeout for the probe. The functions will then spawn a `span_process` process, passing along all the necessary informations.

Once the span is subsequently ended/timed out/failed, the function `send_span` creates a message carrying all the informations and sends it to the C++ server. The formatting of the messages is the following:

```
n:probe name,  
b:Start time (beginning),  
e:End time (end time or deadline),  
s:The status
```

5.2.3 TCP connection

The adapter is composed of two `gen_server` which handle communication to and from the oscilloscope. This `gen_server` behaviour allows the adapter to send spans asynchronously to the oscilloscope.

TCP server

The TCP server `dqsd_otel_tcp_server` is responsible for receiving commands from the oscilloscope. It can be run by setting its IP and port via:

```
-spec start_server(string() | binary() | tuple(), integer()) -> ok |  
  ↪ {error, Reason}
```

The oscilloscope can send commands to the adapter, these commands are:

- `start_stub`: This command sets the adapter as active, it can now send outcome instances to the oscilloscope if the probe's *dMaxs* are defined.
- `stop_stub`: This commands sets the adapter as inactive, it will no longer send outcome instances to the oscilloscope.
- `set_timeout;probeName;timeout`: This command indicates to the adapter to set the *dMax* = timeout for a probe, a limit of the adapter is that `erlang:send_after` does not accept floats as timeouts, so the timeout will be rounded to the nearest integer.

TCP client

The TCP client `dqsd_otel_tcp_client` allows the adapter to send the spans to the oscilloscope. The client connects over TCP to the oscilloscope by connecting to the oscilloscope server's address and opens a socket where it can send the outcome instances.

```
-spec try_connect(string() | binary(), integer()) -> ok.
```

5.3 Parser

To parse the system, we use the C++ ANTLR4 (ANother Tool for Language Recognition) library [48].

5.3.1 ANTLR

According to ANTLR website [48]:

“ANTLR is a parser generator for reading, processing, executing or translating structured text files. ANTLR generates a parser that can build and walk parse trees.”

ANTLR is just one of the many parsers generators available in C++ (`flex/bison` [49], `lex/yacc` [50]). Although it presents certain limitations, its generated code is simpler to handle and less convoluted with respect to the other possibilities.

ANTLR uses an Adaptive LL(*) (*ALL*(*)) parsing strategy, namely, it will “move grammar analysis to parse-time, without the use of static grammar analysis”. [51]

5.3.2 Grammar

ANTLR provides a yacc-like metalanguage [51] to write grammars. Due to page limitations, the grammar we have written can be found in Chapter E.

Limitations

A previous version was implemented in Lark [52], a python parsing toolkit. The python version was quickly discarded due to a more complicated integration between Python and C++. Lark provided Earley(SPPF) strategy which allowed for ambiguities to be resolved, which is not possible in ANTLR.

For example the following system definition presents a few errors:

```
probe = s -> a -> f -> p;
```

While Lark could correctly guess that everything inside was an outcome, ANTLR expects ":" after "s, a, f" and "p". Thus, one can not name an outcome by these characters, as the ANTLR parser generator thinks that an operator or a probe will be next.

5.4 Oscilloscope GUI

Our oscilloscope graphical interface has been built using the QT framework for C++. Qt is a cross-platform application development framework for creating graphical user interfaces [53]. We chose Qt as we believe that it is the most documented and practical library for GUI development in C++. Using Qt allows us to create usable interfaces quickly, while being able to easily pair the backend code of C++ to the frontend.

The interface is composed of a main window, where widgets can be attached to it easily. Everything that can be seen is customisable widgets. This allows for easy reusability, modification and removal without great refactoring due in other parts of the system. We provide a screenshot of the "widget view" in Section B.6.

Chapter 6

Application on synthetic programs

This chapter provides three distinct examples of synthetic applications. Each application was first represented by an outcome diagram in the oscilloscope. It was then instrumented with the adapter to communicate to the oscilloscope. We provide three different examples with simple use cases. Although these use cases may be simple and concise, we will show that the oscilloscope can be a powerful tool in detecting non-linear behaviour with microseconds precision. The examples are:

- A system with sequentially composed outcomes. It serves to show how non-linear behaviour can be detected with the paradigm and the oscilloscope, even when the difference in execution times is minimal. The example leverages M/M/1/K queues to show how typical queue behaviour is represented on the oscilloscope.
- Then, we provide two applications with different operators: first-to-finish and all-to-finish. There, we show how these operators can aid in detecting slower components in the system.

6.1 System with sequential composition

We model a first system with two sequentially composed components. We choose to model the two components as M/M/1/K queues.

This is because an average component in a distributed system can be modeled as an M/M/1/K queue. This is due to the exponential inter-arrival rate of messages, the exponential distribution of the execution delays, the buffer size of messages K of a component and its failure rate f . [8]

Let us first provide a refresher about M/M/1/K queues:

- λ : The arrival rate.
- The service time s : is the time it takes to serve a message.
- μ : The service **rate** and $E[s] = \frac{1}{\mu}$
- Offered load: $\rho = \frac{\lambda}{\mu}$

We will control λ to show its effects on the offered load. This is because the offered load can tell much about the system:

- At low load ($\rho < 0.8$) the failure will tend to 0. The system is behaving correctly and the ΔQ will show that, as the delay will tend to 1.
- Once ρ is approaching high load ($\rho > 0.8$) we can observe the failure increasing quickly. However, we can observe the system starting to get bad after $\rho > 0.5$. [8]

6.1.1 System's outcome diagram

The system (Fig. 6.1) has two components **worker_1**, **worker_2**. Each individual component is composed of a queue of size $K = 1000$ and a worker process.

The system sends n messages per second following a Poisson distribution to **worker_1**'s queue. The queue notifies its worker if the worker is not busy. The worker performs N loops of fictional work, they are defined upon start and are done to simulate a component performing a task. Once done, **worker_1** then passes a message to **worker_2**'s queue, which has another queue of size = 1000, who passes the message to **worker_2**'s worker, which does the same amount of loops as **worker_1**. When a worker completes its work, it notifies its queue, freeing one message from its buffer size and allowing the next message to be processed.

If the queue's buffer is overloaded, it will drop the incoming message and consider the execution a failure.

A probe named “*probe*” is defined, which observes the execution from when the message is sent to **worker_1** up until **worker_2** is done.

Lastly, both workers share the same processor, to observe the effects of non-linearity in a distributed setting.

The system can be defined via the previously defined syntax (Section 4.3) as:

```
probe = worker_1 -> worker_2;
```

Figure 6.1: Refined outcome diagram of the system. The labeled coloured lines represent the probes that were inserted. $q_{1,2}$ outcomes represent the queues. $w_{1,2}$ represent the workers. As we do not wish to observe the queues, but the whole behaviour of the worker components, we can insert probes from when the message is received to when the worker loops end. We can imagine that $q_{1,2}$ and $w_{1,2}$ are refinements of outcomes $worker_{1,2}$, this is why the probes names differ from the outcomes they observe.

6.1.2 Determining parameters dynamically

We stated previously that determining parameters is something that must be done with an underlying knowledge of the system (Section 4.1.2). The oscilloscope can provide knowledge of the system. Fig. 6.2 shows an example of worker_1 and worker_2 as observed in the oscilloscope.

The engineer supposes that the workers executions should take a maximum of 4 ms to complete, but doesn't actually know how long the executions should take. The engineer, after having set $dMax = 4ms$, observes the graph Fig. 6.2 on the left in the oscilloscope.

The oscilloscope shows the engineer that their assumptions do not correspond to the actual system ΔQ . The user can then modify the parameters to observe the actual worker's behaviour. By setting $dMax$ to 8 ms, they can observe the worker's ΔQ s failure approaching 0 on the right Figure in Fig. 6.2.

On the other hand, the engineer's assumption could have been what they truly expected from the system. In this case, the oscilloscope tells him that the system is not behaving as expected.

Figure 6.2: **Left:** worker_1 ΔQ with $dMax = 4ms$. (Green, between the arrow): Mean and confidence bounds of ΔQ s in polling window. (1, blue): Observed ΔQ in sampling window. The worker failure tends to 0.25.

Right: worker_1 ΔQ with $dMax = 8ms$. The worker failure now tends to 0.

In both graphs we can observe how the observed ΔQ of the sampling window is not precise. The step function representation of it fluctuates. The mean and confidence bounds provide a more precise representation of the ΔQ s of worker_1 over a polling window.

Low Load

We will send 50 messages per second to observe the system under test to get key properties. The workers do a million loops.

We can observe in the left graph in Fig. 6.3 that the average worker’s execution takes $\approx 33\text{ms}$. We then have $\mu_{worker} = \frac{1}{0.0033s} \approx 300 \text{ req/s}$. Thus, $\rho = \frac{50}{300} = 0.1\bar{6}$, we can assume the system is at low load.

At low load (Fig. 6.3), the system is behaving **linearly**. Recall Section 2.1.9, at low load the sum of the two delays will overlap with the observed total delay. We can observe in the oscilloscope the probe **observed ΔQ** and **calculated ΔQ** confidence bounds overlap.

Figure 6.3: Graphs for $\lambda = 50$. Left: worker_1 ΔQ s. (1, Blue): The observed ΔQ . (Green, between arrows): Observed polling window confidence bounds. Right: “probe” ΔQ s. (1, blue): The sampling window observed ΔQ . (2, red): The sampling window calculated ΔQ . (Magenta, between arrows): the observed and calculated ΔQ s confidence bounds overlapping.

Early signs of overload

At load = 0.5 the system should start showing dependent behaviour. We can observe what happens when $\lambda = 150 \rightarrow \rho = 0.5$.

Recall 2.12, a non-linear system does not obey superposition. The sum of the delay of the workers will deviate from the overall delay of “probe”. In Section 6.1.2, this is the case.

We can start to observe early signs of dependency even at $\rho = 0.5$. The mean of the observed ΔQ is deviating from the calculated one. At the 50th percentile the deviation is *minimal*, around 0.4 ms. Nevertheless, the precision of the paradigm and the oscilloscope allows even for these minimal deviations to appear on the graphs, being able to recognise *non-linearity* and *early signs of overload*.

The superposition principle is not respected anymore, there is apparent **non-linearity**, and the fact that ΔQ can recognise non-linear behaviour with **0.4ms precision** is impressive. The oscilloscope is a powerful tool that can help assess dependent behaviour in running systems.

Figure 6.4: **Left:** The “probe” ΔQ s as observed in a snapshot. **Right:** Zooming in the oscilloscope, we can observe a slight, but noticeable deviation. (1) Sampling window observed ΔQ . (Arrow, blue, above): Its confidence bounds. (2) Sampling window calculated ΔQ . (Arrow, red, below): Its confidence bounds. The observed polling window confidence bounds are $>$ than the calculated ΔQ bounds. The deviation at the median is of 0.4 ms, but it is noticeable in the oscilloscope.

High load

Performance degradation at 0.5 offered load is already remarkable, the observed ΔQ s and the calculated ones are slowly but surely deviating. The difference is seemingly minimal, but noticeable. We can go even further and observe the system under high load situations (Fig. 6.5). We set $\lambda = 250 \rightarrow \rho = 0.83$, just above the high load threshold.

Figure 6.5: Graphs for $\lambda = 250$. **Left:** worker_1 observed ΔQ with its confidence bounds.

Right: probe ΔQ s. (1, blue) Sampling window observed ΔQ with its confidence bounds, (2, red) Sampling window calculated ΔQ inside its confidence bounds.

This confirms what is expected by queueing theory, ΔQ is capable of observing the basic observation requirements and capable of recognising dependency. While what is expected by the worker's observed ΔQ is a nice normally distributed CDF with little to no failure. What we can observe on the probe is degraded performance in its observed ΔQ mean.

Due to dependency, high load and processor utilisation, the queue is filling up and the workers are taking more time to complete. If you recall Fig. 6.3, the worker's delay distribution was less than the current one. We can see that it has completely degraded, with the average request taking almost double the time as under normal queueing conditions.

Further degradation can be observed by increasing $\lambda = 300, 350 \rightarrow \rho \geq 1$ (Fig. 6.6).

Figure 6.6: **Left:** (1) probe observed ΔQ and confidence bounds for polling window. (2) probe calculated ΔQ and confidence bounds for polling window at $\lambda = 300$. **Right:** probe ΔQ s at $\lambda = 350$.

The system degrading is clear, the ΔQ s show how almost all messages are being dropped or take $> dMax$. We can now look at triggers and how they can be useful to diagnose such cases.

Triggers

By observing the system under test in high load cases, we can set the load trigger by setting the sampling window to 1 second and trigger when outcome instances $\gtrapprox 150$. We can also set a trigger based on observation of the running system.

QTA trigger Recall the previous definition of ΔQ (Section 4.1.3), by observing the system, we create a QTA for the probe “probe” with: 25% = 0.0075 s, 50% = 0.0125 s, 75% = 0.015s and minimum success rate = 0.9.

By setting the trigger to fire for $\Delta Q_{obs} < QTA$. We captured a handful of snapshots. Here, $\lambda = 150$.

Figure 6.7: **Left:** Snapshots for fired triggers.

Right: (1, blue) Observed ΔQ in sampling window violating QTA (3). The confidence bounds for the observed polling window (blue, arrow, below) show the system deteriorating. The sampling window calculated ΔQ (2) is behaving worse than its confidence bounds (red, arrow, above). The system is overloaded, degrading and showing non-linear behaviour, this is captured by the QTA violation.

Instances trigger QTA triggers can help detect non-linearity even before it becomes evident.

By knowing the inner details of the system, setting a QTA on the number of instances can be useful. Fig. 6.8 is an example of a fired trigger on the number of instances. Even though the QTA requirement isn't being violated, the number of instances fires a trigger, where the user can observe that the system is showing early signs of overload.

Figure 6.8: Graph of a snapshot for a fired trigger observing the load of a probe. (1) Observed ΔQ confidence bounds. (2) Calculated ΔQ confidence bounds. The trigger fires for observed load > 150 in a sampling window of 1 second. Even if the QTA requirement (step function) is not being violated, the system is showing early signs of non-linear behaviour.

6.2 Detecting slower workers in operators

6.2.1 First to finish application

Next, we provide a synthetic application modeling an application that can be modeled by a first to finish operator.

Recall the previous FTF graph Fig. 2.5. Assume a send request to “the cloud” that waits for a response or a timeout, it is modeled by an FTF operator. [8]

Using the wrong operator

What happens if the wrong operator is chosen to represent the causal relationships between the outcomes? What if the user believes that the system diagram is the one we presented before in Fig. 6.1 (1 in Fig. 6.9)? The result on the oscilloscope will clearly show that something is wrong.

```
ftf = worker_1 -> worker_2; (1)
... = f:ftf(worker_1, worker_2); (2)
```

Figure 6.9: Two outcome diagram definitions proposed by the engineer for ftf.

On the left in Fig. 6.10, we can observe how the sampling window **calculated** ΔQ and its confidence bounds (2) are clearly greater than the sampling window **observed** ΔQ (1) and its confidence bounds. This difference tells us that the proposed outcome diagram does not correctly represent the actual system. On the right, if no dependencies are present and the correct operator is chosen (2 in Fig. 6.9), the two ΔQ s (observed and calculated) will overlap, as shown on the right in Fig. 6.10.

Figure 6.10: **Left:** FTF plot **with wrong outcome diagram definition** as shown in the oscilloscope. (1) Observed ΔQ . (2) Calculated ΔQ .

Right: FTF plot **with correct outcome diagram definition** as shown in the oscilloscope. Observed ΔQ and calculated ΔQ overlapping.

Introducing a slower component

Let us introduce a slower worker into the system, we introduce an artificial delay into worker_2 (about 20ms). If the oscilloscope works correctly, the paradigm operations are sound and no dependencies are present in the system, we should not see any difference in the observed and calculated ΔQ s of the FTF operator. Moreover, the FTF ΔQ should be overlaid on top of the slower worker (worker_1). In Fig. 6.11, this is the case, the FTF operator can be overlaid on top of worker_1's graph.

Figure 6.11: **Left:** FTF plot of worker_1 and worker_2, observed and calculated ΔQ overlapping.

Right: worker_1 (1) and worker_2 (2) ΔQ s confidence bounds.

The FTF plot correctly displays how worker_2 does not have an effect on the FTF plot.

6.2.2 All to finish application

We can extend the previous application to an all-to-finish operator. This operator can for instance represent parallel work, a task that requires a lot of computation and can be done in separate pieces by separate workers. [8]

Introducing a slower component

Like we did for the FTF operator, let's introduce a slower worker into the system. We introduce a slight delay to show how even a few milliseconds can be noticeable right away by a keen eye (or by triggers, which avoids having to look constantly at the graphs). Worker_2 is 2ms slower.

The difference in the worker's ΔQ can be noticed with $\Delta Q_{w2} > \Delta Q_{w1}$ on the right in Fig. 6.12. The difference can then be observed in the all-to-finish plot on the left in Fig. 6.12, where the operator's ΔQ s confidence bounds (both observed and calculated) can be overlaid on top of worker_2 ΔQ . This shows once again that the ΔQSD algebraic foundation is sound. Moreover, the oscilloscope can be useful in detecting slower components in a system.

Figure 6.12: **Left:** ATF plot with polling window confidence bounds for observed and calculated ΔQ . **Right:** Worker's plots, worker_2 is slower than worker_1.

These plots show the usefulness of ΔQSD , the system can be decomposed to understand which part of the system is showing hazards thanks to the notion of outcome diagrams. Furthermore, the causal relationships can be observed to determine the behaviour of a part down to the single component.

Chapter 7

Performance study

This chapter evaluates the components and operations we introduced in previous sections, analysing their performances.

- We first evaluate the convolutions algorithms we previously introduced. Previously, stated that naïve convolution would have $\mathcal{O}(N^2)$ time complexity, while FFT convolution would have $\mathcal{O}(N\log N)$ complexity. We will evaluate both algorithms to see if what we observe corresponds to theory.
- We then evaluate the ΔQ adapter API performances, to see the overhead it introduces into a system.
- Lastly, we want to evaluate the QT framework plotting performances, we believe it is the weakest link in the oscilloscope and thus want to evaluate the QtCharts class when plotting ΔQ s.

7.1 Convolution performance

We implemented two versions of the convolution algorithm as described before, the naïve version and the FFT version F.4.3. We compared their performance when performing convolution on two ΔQ s of equal bins. In theory, we should observe the naïve version delay quickly grow, while the FFT version have a log-linear growth. We observe the result in Fig. 7.1.

As expected, the naïve version has a time complexity of $\mathcal{O}(N^2)$ and quickly scales with the number of bins. This is clearly inefficient, as a more precise ΔQ will result in a much slower program.

As for the FFT algorithm, it is slightly slower when the number of bins is lower than 100. This is due to the FFTW3 routine having slightly higher overhead. Moreover, if we look closer at the FFT graph, we can observe slight increases after we surpass powers of 2 (e.g. at $600 > 512$, $300 > 256 \dots$). This is because the algorithm is based on ΔQ s which are zero-padded to the nearest power of 2, to make the calculation faster.

While we limit the number of bins to 1000 right now, this limit could potentially be

Figure 7.1: Performance comparison of FFT convolution and naïve convolution algorithms.

increased as the FFT convolution algorithm is very efficient (0.5 ms for 1024 bins).

7.2 ΔQ adapter performance

We evaluated the performance of the adapter to measure its impact in a normal execution, namely we tested the following calls which represent a normal usage of the adapter.

- `start_span` \rightarrow `end_span`.
- `with_span` with the following function: `fun()` \rightarrow `ok`.
- `start_span` \rightarrow `fail_span`.

We ran the simulation for 25000 subsequent iterations, the results are shown in Fig. 7.2:

Figure 7.2: Adapter performance evaluation.

The overhead is minimal, around 10 microseconds on average to start and end/fail a span. The same cannot be said about with span, the increased overhead is nevertheless due to a function needing to be called inside it for it to record a span.

7.3 GUI plotting performance

We evaluated the performance of the GUI plotting routine. We evaluated the routine when plotting the sampling window observed ΔQ , the mean and confidence bounds of the polling window of observed ΔQ s. The procedure is the same for an observed and calculated ΔQ , so we would need to double the results we have to obtain the total time for the plot. The routine first prepares the ΔQ s, creating vectors of `QPointF` (a Qt class representing a point for a `QtChart`), representing all the x and y values of the ΔQ s CDF. The vectors are created for the lower bound, the upper bound, the mean of the window of ΔQ s and the observed ΔQ .

Then, once the vectors are prepared, Qt replaces the old points with the new points for every series being plotted.

Figure 7.3: Performance of plotting sampling window and polling window observable ΔQ . **(Blue, circle)**: QPointF vectors setup performance. **(Orange, square)**: Plotting performance. **(Black, dotted)**: Sum of the previous two.

The result scales up to 2 ms for 1000 bins. We believe that these performances are the choke point of the oscilloscope. If we were to plot the calculated ΔQ and its confidence bounds, the time increase would be twofold. If the sampling rate was 100ms, some frames would probably be skipped if the number of bins = 1000. The results may nevertheless be explained by the specifications of the PC where we ran the tests, namely by the CPU and the GPU (Chapter A).

Chapter 8

Conclusions and future work

As we introduced the thesis, its background and current problems we think exist in observability tools, we set out a clear goal: design a graphical dashboard, the **ΔQ oscilloscope**, to observe running Erlang applications and plot the system's behaviour in real time thanks to the ΔQSD paradigm. While we can not say that we are fully finished with the development of the oscilloscope, we can clearly say that a **working prototype** that reflects the theoretical findings of the paradigm and fulfills the initial goals was created.

This was successfully achieved thanks to multiple important implementations which make it fast, reliable and moreover capable of accurately detecting deviations from required behaviour.

The ΔQ adapter, named `dqsd_otel`, an Erlang application which is able to work alongside OpenTelemetry to add the notion of failure according to ΔQSD to spans. The adapter can communicate data about outcome instances from a running system directly to the oscilloscope and can directly receive commands from the oscilloscope. The `gen_server` behaviour of the adapter client and server allows for this to be done fast and asynchronously.

The ΔQ oscilloscope, a fully fledged Qt dashboard application that is able to observe running systems and provide real time plotting capabilities to the user. Moreover, it provides full control over to the user of the outcome diagrams, the parameters of probes, their QTAs, the triggers they want to set for a given probe, a system of snapshots which allows observing the system as if it was frozen in time. In fine, the FFT convolution algorithm allows us to scale down from $\mathcal{O}(n^2)$ complexity to $\mathcal{O}(n \log n)$, bringing the time to provide precise insights significantly down.

The synthetic applications further prove the oscilloscope's usefulness in detecting early signs of overload and dependent behaviour. This reinforces the solid theoretical basis of ΔQSD , which we remind has already been applied in many industrial projects.

Many crucial features are still missing from the dashboard, and it could require less code modifications in the Erlang side. The next important step of the oscilloscope is its trial in a true distributed application.

8.1 Future improvements

We list here some improvements which could be made to both the oscilloscope and the adapter.

8.1.1 Oscilloscope improvements

- The oscilloscope could be turned into a **web app**, we feel that a C++ oscilloscope is a good prototype and proof of concept, but its usability would be greater in a browser context. It would be great as a plugin for already existing observability platforms like Grafana.
- A wider selection of **triggers**, as of writing this thesis, only the QTA trigger and load are available, this is a limitation due to time constraints. Nevertheless, triggers can be easily implemented in the available codebase.
- **Better communication between stub - server - oscilloscope.** The current way of sending outcome instances may be a limiting factor under high load, if hundred of thousands of spans were to be sent, the current way the server and oscilloscope are tied together may throttle communications. TCP socket connections could quickly become the chokepoint which makes the oscilloscope temporarily unusable.

Future improvements on the server side could implement epoll system server calls to make the server more efficient; **Detaching server from client**, as of right now, the oscilloscope and the server are tied together, using ZeroMQ to assure real time server-client communications could be an interesting solution to explore.

- **Improve real time graphs.** The class QtCharts does not perform correctly with high frequencies update. Moreover, since we are plotting multiple series (from a minimum 4 to a maximum of 9) per probe, which allows up to 1000 bins per probe, the performance quickly degrades with more probes being displayed. A better graphing class for Qt could definitely improve the experience.
- **Saving probe parameters:** As of writing this thesis, there is no way to save the parameters one may have set.
- **Deconvolution:** An important aspect of Δ QSD, which was not introduced in this paper is deconvolution. It is used to check for infeasability in system desing. Since convolution has already been implemented, this could be integrated using the FFTW3 library.
- **Exporting graphs:** The graphs can only be observed in the oscilloscope and have no way to be exported to other programs via standard formats.
- **Many more:** This oscilloscope is just a start and part of the dissemination project of Δ QSD. If we were to list everything we may want to add, it would take many pages. What we provide is a sufficient enough basis to provide possibilities to observe a running system and understand the power of Δ QSD in analysing its behaviour.

8.1.2 Adapter improvements

- As suggested by Bryan Naegele, a member of the observability group of Erlang, the adapter, instead of working on top of OpenTelemetry, could be directly included inside the context of a span by using the `ctx` library [54], which provides deadlines for contexts, propagating the value in `otel_ctx`, making it available to the OpenTelemetry span processor. Leveraging `erlang:send_after` as we already do, we could create outcome instances with telemetry events to handle successful executions and timeouts. The span processor will then be responsible for creating outcome instances, without creating the need for custom functions in the adapter, like we have now.

8.1.3 Real applications

A flaw of the oscilloscope and adapter is that they have not been tested on real applications, while their usefulness has been proven on synthetic applications, the lack of real life applications is an evident weakness.

8.1.4 Licensing limitations

Lastly, a notable limitation is created by **Qt**, namely, QtCharts. The usage of Qt does not allow us to release our project under BSD/MIT licenses, but rather a GPLv3 one (we cannot release it under LGPL due to QtCharts). [55]

Appendix A

Tests specifications

The tests were run on a laptop with the following specifications.

- OS: Manjaro Linux x86_64, Kernel: 6.12.11-1-MANJARO
- CPU: Intel i5-6300U (4) @ 3.000GHz
- GPU: Intel Skylake GT2 [HD Graphics 520]
- RAM: 16 GB DDR4 SDRAM—2133MHz

Appendix B

Oscilloscope screenshots

B.1 System/Handle plots tab

Here is a screenshot from the tab to create the system and handle plots (Fig. B.1).

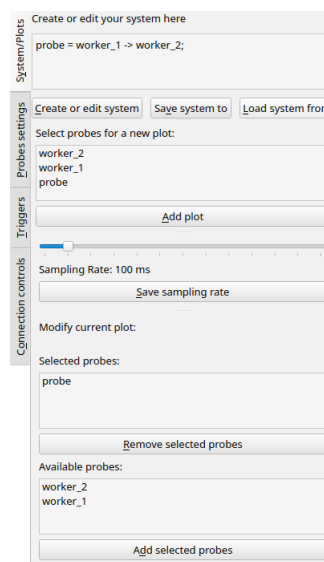

Figure B.1: System/Handle plots tab in oscilloscope.

B.2 Parameters tab

Here is a screenshot of the parameters tab, with a set QTA showing up on a plot (Fig. B.2).

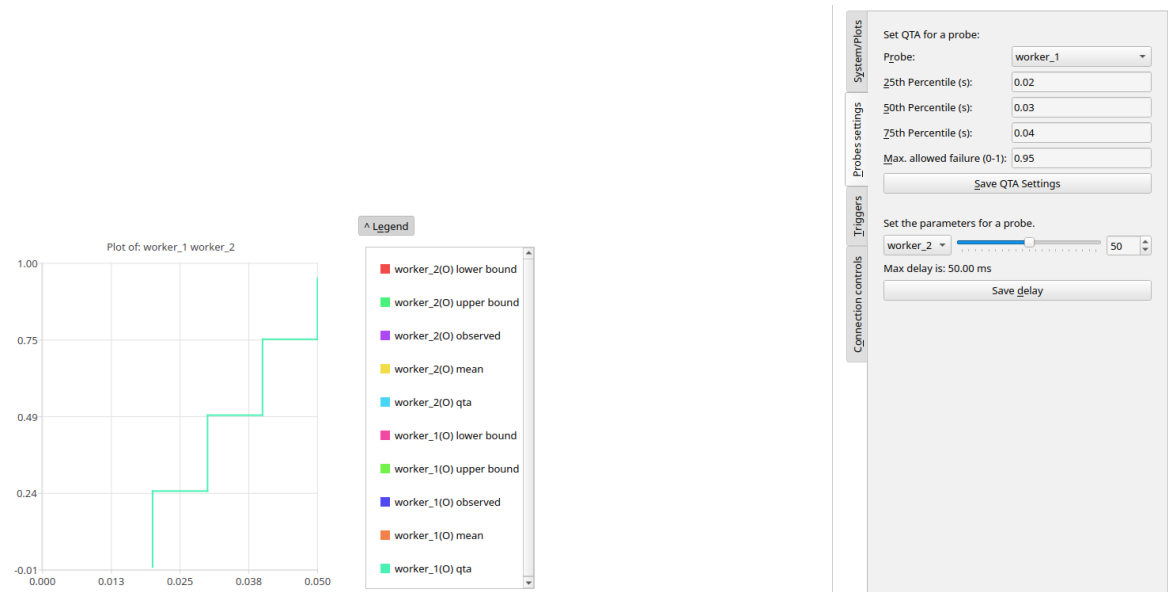

Figure B.2: Parameters tab in oscilloscope. The QTA set for worker_1 can be seen on the plot.

B.3 Triggers tab

Here is a screenshot of the triggers tab, with saved snapshots, QTA violation set for probe and a running plot (Fig. B.3).

Figure B.3: Triggers tab in oscilloscope. The snapshots for the whole system are saved and can be observed.

B.4 Snapshot window

Here is a screenshot from the window observing a snapshot (Fig. B.5).

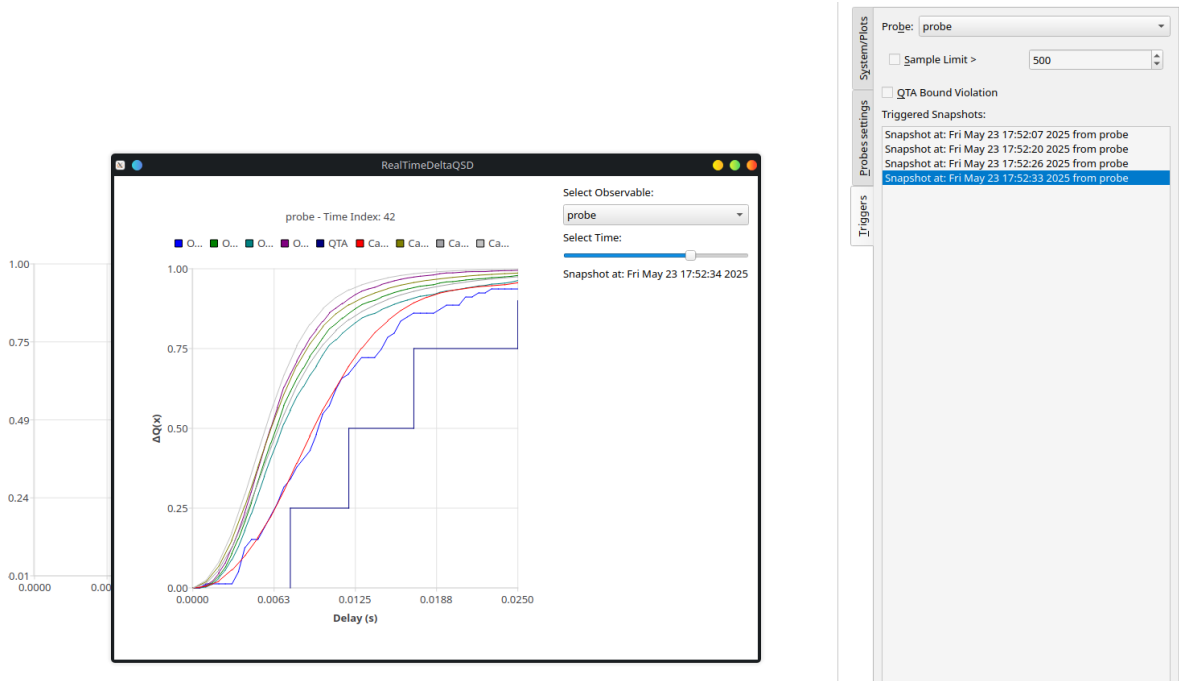

Figure B.4: Snapshot window (above) over the running oscilloscope below.

B.5 Connection controls

Here is a screenshot of the available controls in the oscilloscope (Fig. B.5).

Figure B.5: Connections control tab in the oscilloscope with the erlang and oscilloscope endpoints.

B.6 Widget view of GUI

The GUI is composed of multiple building block, the widgets. The screenshot we provide here highlights the multiple widgets present in the GUI (Fig. B.6). These widgets could be broken down into the multiple subwidgets that compose them.

Figure B.6: Widget view of the oscilloscope dashboard.

Part I

User manual

Appendix C

How to download and launch

To download the oscilloscope, go to the GitHub repository (<https://github.com/fnieri/DeltaQOscilloscope/>) and go to the releases page, there, you will find the different versions of the oscilloscope. For instruction purposes, we have made a pre-release to show where to find it.

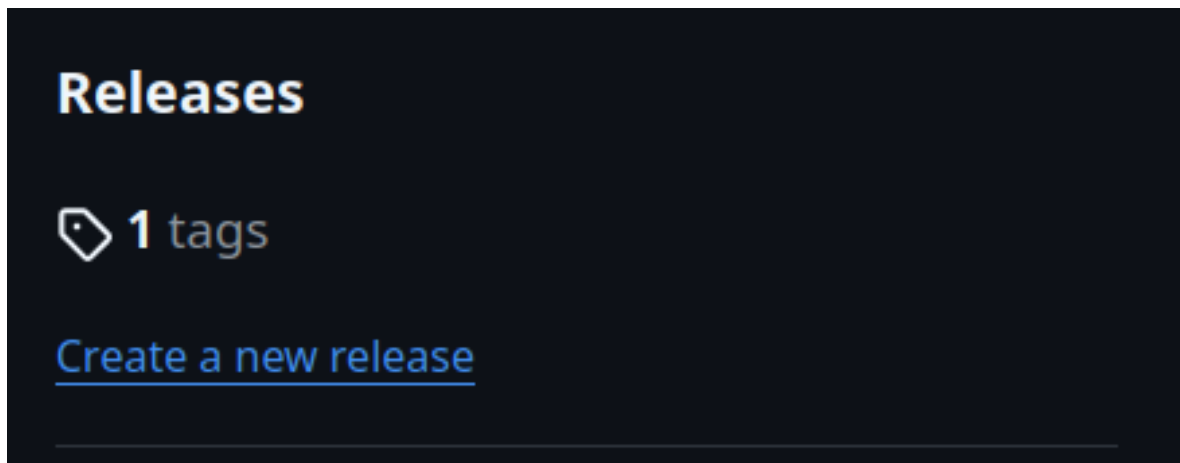

Figure C.1: Releases tab.

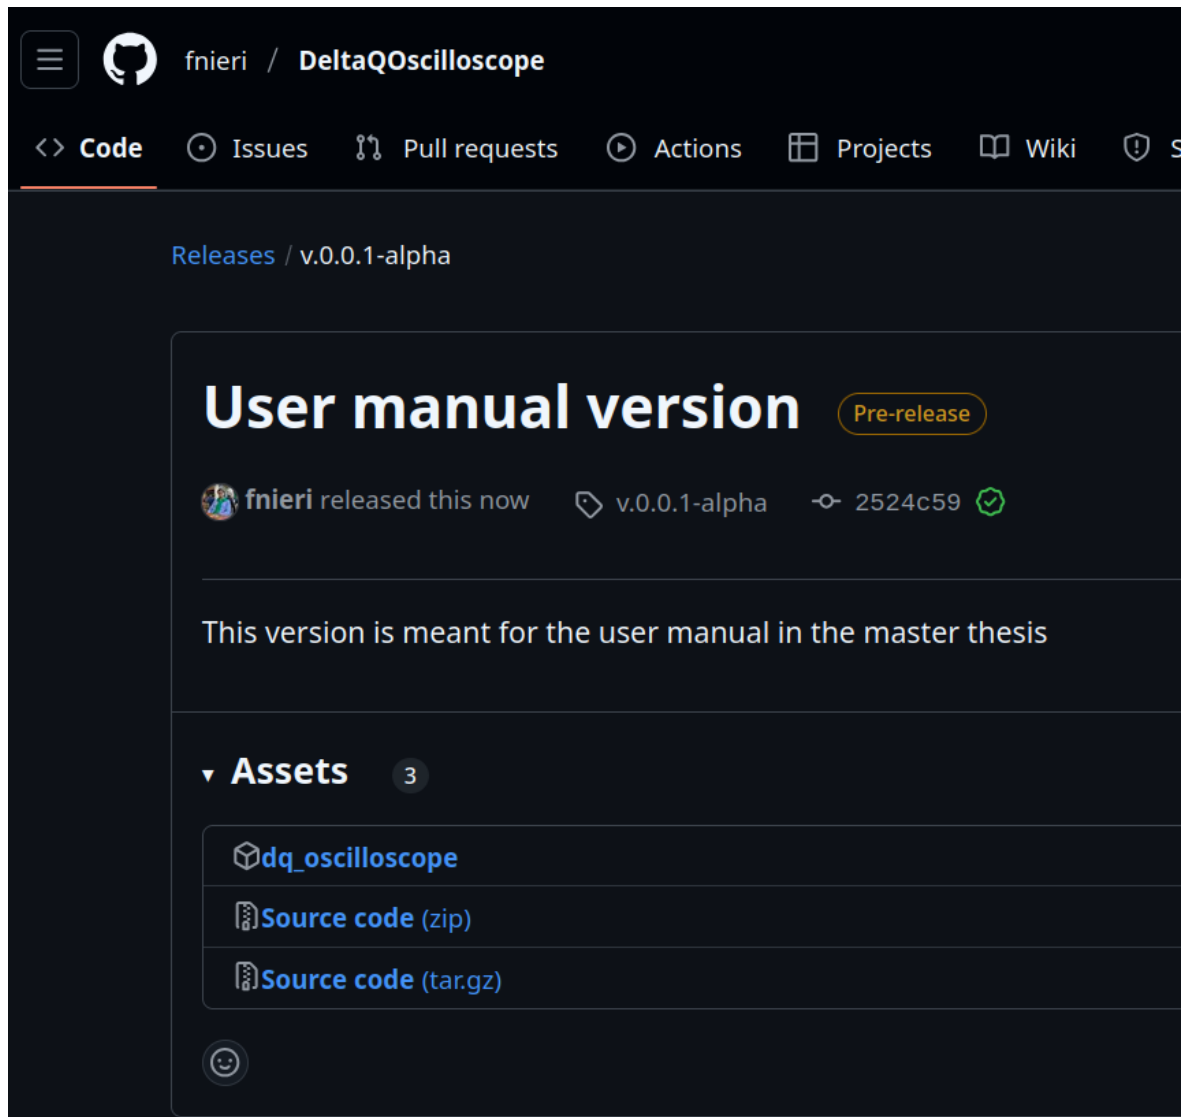

Figure C.2: Sample release

The `dq_oscilloscope` binary is the binary to download. By launching the binary on the CLI with:

```
./dq_oscilloscope
```

The oscilloscope will launch.

Appendix D

Oscilloscope: How to use

D.1 Establishing the adapter - oscilloscope connection

To connect to the oscilloscope to the server, you first need to start the oscilloscope server by setting the oscilloscope listening IP and port on the dashboard (Fig. D.1).

Figure D.1: Widget to set server endpoint in the oscilloscope

If the server cannot start, a popup will appear with the error.

Once this is done, the adapter can establish a connection to the oscilloscope to send outcome instances (Fig. D.2). The adapter can now connect to the oscilloscope server.

```
1> dqsd_otel_tcp_client:try_connect("127.0.0.1", 8080).  
ok  
dqsd_otel: Adapter connected to 127.0.0.1:8080  
2> □
```

Figure D.2: Establish connection from adapter to oscilloscope.

We now need to start the listener on the adapter (Fig. D.3).

```
2> dqsd_otel_tcp_server:start_server("127.0.0.1", 8081).
dqsd_otel: Listening socket started on "127.0.0.1":8081
ok
3> 
```

Figure D.3: Adapter starting listener for commands and parameters from the oscilloscope

If an error may arrive during the start-up of the listener, it will be printed out.

Now, we can connect the oscilloscope to the adapter by setting the listener endpoint (Fig. D.4).

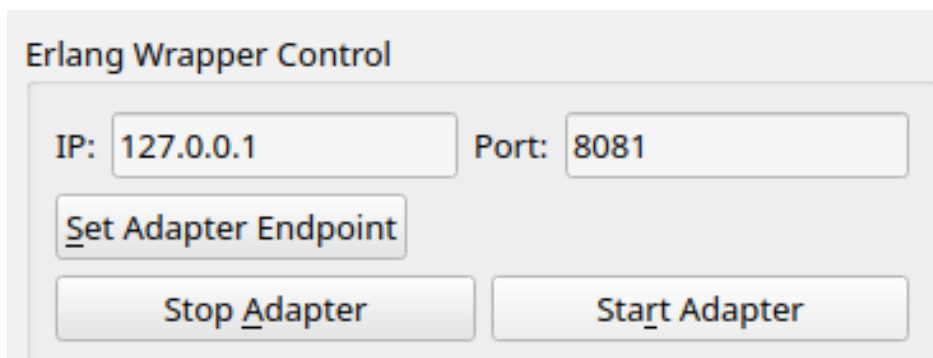

Figure D.4: Set Erlang listener endpoint in oscilloscope.

If the server cannot connect, an error will pop up. Once connected, the server can start and stop the adapter sending of the spans by clicking the two buttons below.

D.2 Sidebar: Outcome diagram and plots

D.2.1 Creating the system/outcome diagrams

You need to provide a textual description of your outcome diagram following the syntax which was defined previously (Section 4.3). You can create your system by clicking on the **Create or edit system** button (Fig. D.5). If the parser successfully parsed the text, your system will be created, and you can start setting the parameters for your probes.

Create or edit your system here

```
probe = worker_1 -> worker_2;  
send = o1 -> o2;  
sys = s:probe -> s:send;
```

Create or edit system

Save system to

Load system from

Select probes for a new plot:

worker_2
o1
worker_1
o2
probe
send
sys

Add plot

Figure D.5: After selecting create system, if the system definition is correct, the inserted probes will be available to be plotted.

If the parser does not correctly parse the text, it will show a popup indicating the line where the error was produced and what it was expecting (Fig. D.6). If there is a cycle, it will specify where it found the cycle.

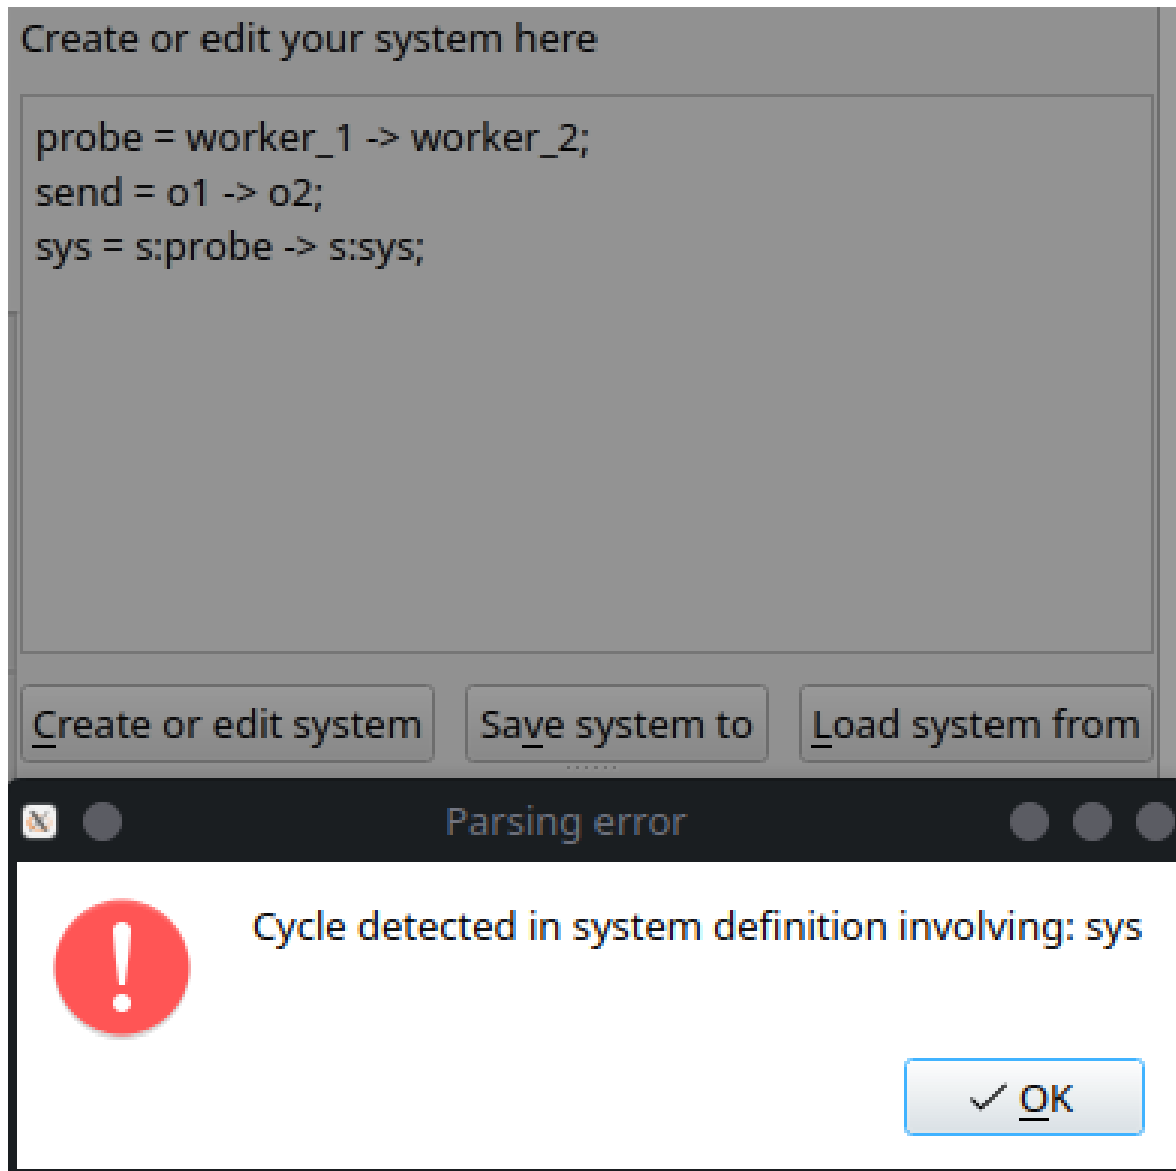

Figure D.6: Creation of a system with a cycle

D.2.2 Saving the system definition

The button **Save system to** gives you the possibility to save the textual definition of the outcome diagram to a file. You can save the file to any extension, but preferably the file will have the **.dq** extension (Fig. D.7).

D.2.3 Loading the system definition

The button **Load system to** gives you the possibility to load the textual definition of the outcome diagram you may have previously saved to a file (Fig. D.7). As for the extension, you can load any file extension.

Figure D.7: Example popup where the user can select a file where the system definition is loaded.

D.2.4 Changing the sampling rate

The user can set the sampling rate via the slider in this tab (Fig. D.8):

Figure D.8: Slider widget.

D.2.5 Managing the plots

Once you have your system defined you can start adding plots of the ΔQ s of the probes you inserted in your system.

Adding a plot

Multiple probes can be added at once in your plot, you can select the probes you want to add to a new plot by selecting them in the “**Add a new plot**” section (Fig. D.9). Then by clicking the “**Add plot**” button, the selected probes will be added to the plot (Fig. D.10).

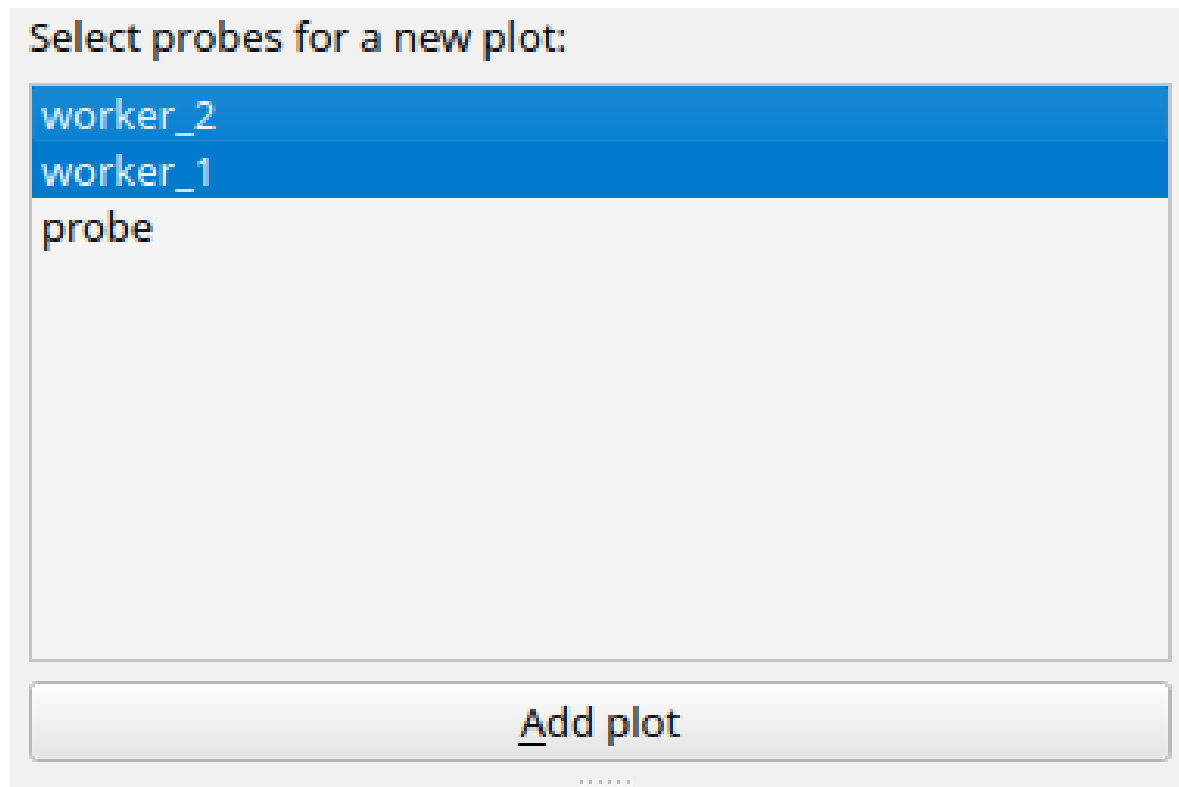

Figure D.9: Selecting the probes to add to a plot

Figure D.10: After adding the probe's to a plot, if the adapter is already sending spans, the plot will show the real time ΔQ s.

Editing a plot

You can remove the probes you have added to the plot by first clicking to it, this sets the plot as the **selected plot**. Once you have clicked the plot, a section will pop up beneath the rest of the controls on the sidebar.

In the section there are two subsections, one which shows the selected components which form the plot (those you have added previously), and the available components. You can select the probes you want to remove in the “**selected probes**” zone, by clicking “**Remove selected probes**” the components will be removed from the plot. Inversely, in the “**Available probes**” section, you can select the plots you want to add, and by clicking “**Add selected probes**” you can add the selected components to the selected plot (Fig. D.11).

Figure D.11: To modify a plot, click on the probe you want to remove or add. Here, for example, worker_1's probe was added by selecting it below and clicking "Add selected probes".

D.2.6 Removing a plot

By left-clicking the plot, a popup appears, you can click "**Remove plot**", this removes it from the selected plot (Fig. D.11).

D.3 Sidebar: Probes settings

Now that you have create your outcome diagram, you can modify the probes settings to set the $dMax$ you want and the QTA you desire.

D.3.1 Setting a QTA

You can set a QTA in the "**Set a QTA**" section, there you are presented with the possibility to:

- Select the probe for which you want to set the QTA.
- Set the QTA at the three percentiles (25%, 50%, 75%), the text to the left indicates which percentile is which. You need to set the delay in seconds.
- The minimum amount of successful events you can allow, which is bigger than 75%.

Of course, for the delay of the QTA at three percentiles, the delay at the percentile must be higher or equal than the delay at the previous percentile and higher than 0.

By pressing "*Save QTA settings*" you will save the QTA for the defined probe. Fig. D.12 shows how to do this.

D.3.2 Setting the parameters of a probe

You can set the parameters for a probe in its section. To the left you can select the probe you want to set the parameter for. We provide a slider (which goes from -10 to 10) for the n parameters, to the right of the slider, you can select the number of bins for the probe. The maximum delay calculated will be shown below.

Once you press "**Save delay**", a message to the erlang adapter will be sent, which will set the maximum delay you have set in the adapter. Fig. D.12 shows how to do this.

Sidebar

Probes settings

Triggers

Set QTA for a probe:

Probe: probe

25th Percentile (s): 0.1

50th Percentile (s): 0.25

75th Percentile (s): 0.5

Max. allowed failure (0-1): 0.95

Save QTA Settings

Set the parameters for a probe.

probe

1000

Max delay is: 62.50 ms

Save delay

Figure D.12: Probes settings tab. Above: QTA settings. Below: Probe parameters settings.

D.4 Triggers

In the triggers section you can define which triggers to apply for a given probe, once selected, they will be automatically activated.

Once a trigger is triggered, the oscilloscope will keep recording the system for a few seconds. Once stopped, under the "snapshots" section, you can click the snapshots to view them in a separate section, there, you can observe the ΔQ s of all the probes before and after the trigger was triggered. You can discard the snapshot by left clicking on it and clicking "*Delete snapshot*".

Figure D.13: Examples of the QTA being set for a probe "probe". Once a trigger is fired, the resulting snapshot from the fired trigger will be available under "Triggered snapshots".

D.5 Snapshots

The snapshots can be observed to look at the state of the system, before, during and after the trigger has been fired.

By clicking on the snapshot in the "triggered snapshots" section, a new window will popup where you can observe the system. A slider allows you to move backwards and forwards in time, observing the state of a probe in time.

Figure D.14: Example of a snapshot, to the left, the graph at time t . To the right, the time of the graph on the left and a slider to advance backwards and forwards. As of right now, you can only select a probe at a time.

D.6 Instrumenting the Erlang application

D.6.1 Including the adapter

The Erlang project you need to instrument needs to include the adapter in its dependencies, to do that, you need to include it in your dependencies.

```
%your_app.app.src
{application, otel_getting_started, [
  ...
  {applications, [
    kernel,
    stdlib,
    opentelemetry,
    opentelemetry_api,
    opentelemetry_exporter,
    dqsdtel
  ]},
  ...
]}.

{deps, [
  {opentelemetry, "~> 1.3"},
  {opentelemetry_api, "~> 1.2"},
  {opentelemetry_exporter, "~> 1.0"},
]}
```

```
{dqsd_otel, {git, "https://github.com/fnieri/dqsd_otel.git", {tag,  
  ↳ "the_latest_version_on_git"}}}  
}]}
```

Once you have the dependencies set up you can begin creating outcome instances for the oscilloscope.

(**Note:** If the project was to change name, you can still find the project in <https://github.com/fnieri/>).

D.6.2 Starting spans

To start spans you need to call:

```
{ProbeCtx, Pid} = dqsd_otel:start_span(<<"probe">>, #{attributes =>  
  ↳ [{attr, <<"my_attr_5o5s10">>}]}})  
or without attributes  
{ProbeCtx, Pid} = dqsd_otel:start_span(<<"probe">>)
```

This will give you the OpenTelemetry context of the probe and the Pid of the process to call upon end. It is left up to you to decide how to carry both in the execution. The function calls OpenTelemetry `?start_span` macro, effectively replacing it.

D.6.3 With spans

To start with spans you need to call:

```
dqsd_otel:with_span(<<"worker_2">>, fun() -> ok, #{attributes =>  
  ↳ [{attr, <<"my_attr">>}]}})  
or without attributes  
dqsd_otel:with_span(<<"worker_2">>, fun() -> ok end)
```

The second attribute is the function you want to evaluate.

D.6.4 Ending spans

To end spans you started with `dqsd_otel:start_span`, you need to call:

```
dqsd_otel:end_span(ProbeCtx, ProbePid)
```

This will end the span on the OpenTelemetry side and end the outcome instance if it hasn't timed out. The function calls OpenTelemetry `?end_span` macro, effectively replacing it.

D.6.5 Failing outcome instances

To fail **custom** spans you need to call:

```
dqsd_otel:fail_span(WorkerPid)
```

Contrary to the other methods, this does not end OpenTelemetry spans, it is let up to you to decide how to handle failure in spans.

Part II

Source Code Appendix

Appendix E

Grammar

This is the grammar for the ANTLR4 parser.

```
1 grammar DQGrammar;
2
3
4 PROBE_ID: 's';
5 BEHAVIOR_TYPE: 'f' | 'a' | 'p';
6 NUMBER: [0-9]+('.'[0-9]+)?;
7 IDENTIFIER: [a-zA-Z_][a-zA-Z0-9_]*;
8 WS: [ \t\r\n]+ -> skip;
9
10 // Parser Rules
11 start: definition* system? EOF;
12
13 definition: IDENTIFIER '=' component_chain ';' ;
14 system: 'system' '=' component_chain ';'? ;
15
16 component_chain
17     : component ('->' component)*
18     ;
19
20 component

F.2 Dashboard

This folder contains the widgets that compose the dashboard.

F.2.1 ColorRegistry.cpp

This class stores all the colors for all the QtSeries, moreover, it generates HSV colors based on the algorithm taken from <https://martin.ankerl.com/2009/12/09/how-to-create-random-colors-programmatically/>.

```
1 #include "ColorRegistry.h"
2 #include <cmath>
3
4 std::unordered_map<std::string, QColor> ColorRegistry::colorMap;
5
6 QColor ColorRegistry::getColorFor(const std::string &name)
7 {
8     if (colorMap.count(name))
9         return colorMap[name];
10
11     int index = colorMap.size();
12     QColor color = generateDistinctColor(index);
13     colorMap[name] = color;
14     return color;
15 }
16
17 // Taken from
18 // https://martin.ankerl.com/2009/12/09/how-to-create-random-colors-
19 // programmatically/
20 QColor ColorRegistry::generateDistinctColor(int index)
21 {
22     const double golden_ratio_conjugate = 137.508; // degrees
23     double hue = std::fmod(index * golden_ratio_conjugate, 360.0);
24     QColor color;
25     color.setHsvF(hue / 360.0, 0.7, 0.95); // Saturation and Value
26     // tuned for brightness
27     return color;
28 }
```

F.2.2 CustomLegendEntry.cpp

This class represents an entry in the plot legend.

```
1 #include "CustomLegendEntry.h"
2 #include <QHBoxLayout>
3 CustomLegendEntry::CustomLegendEntry(const QString &name, const QColor
4     &color, QWidget *parent)
5     : QWidget(parent)
6 {
7     layout = new QHBoxLayout(this);
8     colorBox = new QLabel;
9     colorBox->setFixedSize(12, 12);
10    colorBox->setStyleSheet(QString("background-color: %1").arg(color.
11        name()));
12 }
```

```
10     nameLabel = new QLabel(name);
11     layout->addWidget(colorBox);
12     layout->addWidget(nameLabel);
13     layout->addStretch();
14 }
```

F.2.3 CustomLegendPanel.cpp

This widget represents the legend panel for a plot, with entries corresponding to each series.

```
1  #include "CustomLegendPanel.h"
2  #include "CustomLegendEntry.h"
3
4  CustomLegendPanel::CustomLegendPanel(QWidget *parent)
5      : QWidget(parent)
6  {
7      // Initialize scroll area and configure its behavior
8      scrollArea = new QScrollArea(this);
9      scrollArea->setWidgetResizable(true);
10     scrollArea->setVerticalScrollBarPolicy(Qt::ScrollBarAsNeeded);
11     scrollArea->setHorizontalScrollBarPolicy(Qt::ScrollBarAlwaysOff);
12
13     // Create content widget for the scroll area
14     scrollContent = new QWidget();
15     scrollArea->setWidget(scrollContent);
16
17     // Set up layout for legend entries (aligned to top)
18     legendLayout = new QVBoxLayout(scrollContent);
19     legendLayout->setAlignment(Qt::AlignTop);
20
21     // Set up main layout and add scroll area
22     mainLayout = new QVBoxLayout(this);
23     mainLayout->addWidget(scrollArea);
24     setLayout(mainLayout);
25 }
26
27 /**
28  * @brief Adds a new entry to the legend panel.
29  * @param name The name for the entry.
30  * @param color The color for the entry.
31  */
32 void CustomLegendPanel::addEntry(const QString &name, const QColor &
    color)
33 {

F.3 Outcome diagram

The "diagram" folder contains everything related to outcome diagrams. Due to time related issues, there are some issues with the names. We will explain what each class represents, but it differs from the definitions which are explained in the thesis

F.3.1 Observable.cpp

The observable class represents a generic "observable" element of the outcome diagram, it is the base class for probes, outcome and operators. In this class one can calculate the observed ΔQ , store the outcome instances (samples), set the parameters, set a QTA, add/remove triggers and get a snapshot. It is what we described throughout the whole paper as a probe.

```
1  #include "Observable.h"
2  #include <algorithm>
3  #include <cmath>
4  #include <cstdint>
5  #include <iostream>
6
7  #define MAX_DQ 30
8  Observable::Observable(const std::string &name)
9      : observedInterval(50)
10      , name(name)
11  {
12      observableSnapshot.setName(name);
13  }
14
15  void Observable::addSample(const Sample &sample)
16  {
17      samples.emplace_back(sample);
18      sorted = false;
19  }
20
21  std::vector<Sample> Observable::getSamplesInRange(std::uint64_t
22      lowerTime, std::uint64_t upperTime)
23  {
24      std::lock_guard<std::mutex> lock(samplesMutex);
25      if (!sorted) {
26          std::sort(samples.begin(), samples.end(), [](const Sample &a,
27              const Sample &b) { return a.endTime < b.endTime; });
28          sorted = true;
29      }
30
31      std::vector<Sample> selectedSamples;
```

```

30

Appendix I

Erlang Source Files

I.1 Root

I.1.1 dqsd_otel.erl

The ΔQ adapter, it can start, fail, end spans and start and end with _spans, communicates to the TCP client to send outcome instances to the oscilloscope.

```
1 -module(dqsd_otel).
2 -behaviour(application).
3 -author("Francesco Nieri").
4
5
6 -export([start/0, start_span/1, start_span/2, end_span/2, fail_span
7         /1, with_span/2, with_span/3, span_process/3]).
8 -export([start/2, stop/1]).
9 -export([init_ets/0]).
10 -export([set_stub_running/1]).
11 -export([handle_c_message/1]).
12
13 -include_lib("opentelemetry_api/include/otel_tracer.hrl").
14
15 %% @moduledoc
16 %% `dqsd_otel` is an Erlang module built on top of OpenTelemetry
17 %% to pair with the DeltaQ oscilloscope. It tracks spans start, end,
18 %% uses a custom timeout defined by the user in the oscilloscope,
19 %%
20 %% Features:
21 %% - Span lifecycle management (start/end/fail/timeout)
22 %% - Dynamic timeouts for spans
23 %% - Supports toggling stub behavior at runtime
24 %%
25 %% Usage:
26 %% {Ctx, Pid} = dqsd_otel:start_span(<<"my_span">>).
27 %% dqsd_otel:end_span(Ctx, Pid).
28 %% dqsd_otel:fail_span(Pid)
29
```

```
